A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH.

THURSDAY, NOVEMBER 6, 1890.

PRIESTLEY, CAVENDISH, AND LAVOISIER.

THE *Revue Scientifique* of the 25th ult. contains a translation of the address which I had the honour of delivering to the members of the Chemical Section of the British Association at the recent meeting in Leeds, to which, on the invitation of the editor, M. Charles Richet, M. Berthelot prefixes a letter, of which the following is a translation:—

"I have no direct concern in the republication of Mr. Thorpe's address which you purpose making in the *Revue*. Personally, I have not any reason to complain of his courtesy, and I should have been silent so far as he is concerned, holding that one is not bound to enter into a controversy which is purely critical, where no new fact is alleged, and where the judgment of public opinion suffices to set things in their true place; however, I comply with your request to let your readers know what my opinion is.

"To my mind, nothing is more opposed to truth and justice than the introduction of national prejudices into the history of science. All civilized nations are at one in proclaiming the glory of Newton, the greatest of astromers, and yet the majority of English men of science, refusing to treat his rivals with equity, are not agreed to recognize Leibnitz's rights to the invention of the differential calculus: they are as prejudiced in this respect as was Newton himself. Something analogous occurs in regard to the discoveries which created modern chemistry a hundred years ago.

"Unquestionably, Priestley and Cavendish are recognized by all as great discoverers. I have myself taken pains to describe Priestley's discovery of the principal gases in terms of admiration ('La Révolution Chimique,' p. 39), and especially that of oxygen, which I unreservedly attribute to him (pp. 61–62). I have also detailed, with the encomiums which they merit, the investigations of Cavendish, 'one of the most powerful scientific minds of the last century,' and particularly his fruitful research on (to use Blagden's phrase) the artificial generation of water. But the well-merited praise accorded to these English *savants* does not prevent some of their countrymen from persistently denying the right of Lavoisier to the discovery and co-ordination of those general ideas on which rest our actual conception of matter, more especially in relation to the composition of air and water. This, I venture to repeat, is an incident in the long-standing feud, continually being renewed in the history of science, between the sagacious discoverers of particular facts and the men of genius who frame general theories. The opinion of most Continental men of science seems, however, to be decided on this special point, as may be seen from the judgment given, not only by Dumas, but by Hoefer, in his 'History of Chemistry,' by H. Kopp, in his careful account of the discovery of the composition of water, and by many others. I have merely concurred with them.

"It was in this spirit that I had sought to trace the history of the discoveries which constituted the doctrine of modern chemistry, by faithfully reproducing all its phases, whilst at the same time indicating the continuity of sequence in the facts and the paternity of the ideas. I did this with an impartiality which has brought upon me the reproach that I have been indifferent to the reputation of my countryman—the very opposite to the accusations which are now directed against me.

"As regards the composition of air, it is easy to separate facts from ideas. It is certain that the discovery of oxygen is due to Priestley. But, said Lavoisier: 'If I am reproached for having borrowed my proofs from the works of this celebrated philosopher, at least none will contest my right to the conclusions, which are often diametrically opposed to his.'

"Priestley, obstinately adhering to the theory of phlogiston, regarded his new gas as consisting of the very substance of air deprived simply of its phlogiston; whilst nitrogen, according to him, was formed also of this same substance combined with a complementary portion of phlogiston. He remained faithful to this doctrine, which obscured the true nature of the greater number of chemical phenomena, until the moment when, like Lavoisier, persecuted by his countrymen, who now proclaim his fame, driven from home, his laboratory burnt by a mob, and threatened with death, he fled to America, where he died in sadness and in solitude. Even more unfortunate was Lavoisier!

"But whatever may have been the personal fate of these two great men, if it is true that Priestley discovered oxygen, it is not the less certain that the true theory of the nature of air is due to Lavoisier.

"The history of the composition of water is more complicated. In reality, the discovery of the facts belongs neither wholly to Cavendish—who undoubtedly played a most important part, inasmuch as he gave the impetus towards the definitive solution—nor to Lavoisier, who first established a knowledge of the facts by his public experiments and his published writings—nor even to the two combined. They had predecessors, and at the moment even when the light came, Monge played an essential part in the rigorous demonstration of which Mr. Thorpe apparently has no suspicion. Thus each man's share in this history cannot be settled by a word: we require to follow exactly the gradual progress of experiment and publication. But here, again, if Lavoisier is not the principal discoverer of the facts, it is he who has the incontestable merit of having furnished the exact interpretation of the phenomena, freed from the mists of phlogiston, to which Cavendish seems to have remained faithful to the day of his death.

"I have elsewhere laid bare all these facts, and I have no intention of reproducing here the details of a controversy exhausted even in Lavoisier's time, and in which Mr. Thorpe does no more than reproduce the unjustifiable imputations of Blagden, who, impelled by passion, went so far as to interpolate and falsify, with his own hand, the manuscript memoirs of Cavendish, in order to gain arguments in support of his accusations.

"Moreover, nothing more decisively establishes the part played by Lavoisier, and his right to the institution of our modern theories, than the letter of a contemporary English *savant*, Black, as celebrated for his discoveries in physics as in chemistry, and who might have put forward claims on his own account. In 1791 he wrote to Lavoisier, in a letter equally honourable to both :—'The numerous experiments which you have made on a large scale, and which you have so well devised, have been pursued with so much care and with such scrupulous attention to details that nothing can be more satisfactory than the proofs you have obtained. The system which you have based on the facts is so intimately connected with them, is so simple and so intelligible, that it must become more and more generally approved and adopted by a great number of chemists who have long been accustomed to the old system. . . . Having for thirty years believed and taught the doctrine of phlogiston as it was understood before the discovery of your system, I, for a long time, felt inimical to the new system, which represented as absurd that which I had hitherto regarded as sound doctrine; but this enmity, which sprang only from the force of habit, has gradually diminished, subdued by the clearness of your proofs and the soundness of your plan.'

"We can but hope to see the day when the scientific men of England will conform to the opinion of one of the most illustrious of their countrymen.

"M. Berthelot,
"of the Institute."

I quite agree with M. Berthelot that nothing is more opposed to truth and justice than the introduction of national prejudices into the history of science. It was for that reason that I felt compelled, in the Leeds address, to protest against the spirit and bias of the accounts of the discovery of the facts relating to oxygen and the composition of water given in "La Révolution Chimique." Although M. Berthelot's letter somewhat confuses the issues, there is, in reality, but small difference between us. What I ventured to criticize was the general tone and tendency of M. Berthelot's argument, which seems to palliate, and even to justify, Lavoisier's pretensions to a discovery in which he has no right even to be considered as a participator. M. Berthelot now tells us, in his letter that he attributes the discovery of oxygen unreservedly to Priestley. So far so good. It is something gained to have thus secured such an unqualified statement from one who occupies the position of authority in the world of chemistry in France that is enjoyed by the present Perpetual Secretary of the Academy. We may well hope, therefore, that this particular question has been finally set at rest.

M. Berthelot need not ask British men of science to conform to the opinion of Black. They already do so. That to Lavoisier, and to Lavoisier alone, belongs the merit of having effected the overthrow of the theory of phlogiston, and of having to that extent laid the foundation of modern chemistry, is not questioned on this side of the Channel. So far as I know, it has only been among Lavoisier's own countrymen that any doubt on this point has been raised. We all remember the passionate scorn with which Lavoisier repudiated and protested against the attempts of his compatriots to rob him of his rights: "Cette théorie n'est donc pas comme je l'entends dire—la théorie des chimistes français; elle est la *mienne*, et c'est une propriété que je réclaime auprès de mes contemporains et de la postérité." It is true, as M. Berthelot implies, that Black has claims. Lavoisier himself admits as much. It would be easy, if it were not beside the points at issue, to match the letter which M. Berthelot quotes, by others from Lavoisier in which he ascribes to Black the germs of his doctrine. M. Berthelot, I repeat, confuses the issues. This particular point was never raised by me in the address. What I said was:—"Two cardinal facts made the downfall of phlogiston complete—the discovery of oxygen, and the determination of the compound nature of water. M. Berthelot's contention is, that not only did Lavoisier effect the overthrow, but he also discovered the facts." I, in common, I venture to assert, with every British chemist, admit unreservedly that Lavoisier effected the overthrow, but we deny that he discovered the facts. It is altogether beside the question for M. Berthelot now to say in effect:—"Have I not praised your men of science, and thereby drawn down upon myself the wrath of my countrymen? And yet you are not satisfied!' We are sorry for M. Berthelot: he is in the position of the man with many friends, and his friends for the moment are a little angry. He has either not the courage of his convictions, or he has halted between two opinions—with the usual consequences.

With respect to the discovery of the compound nature of water, M. Berthelot now takes up a different position from that which he occupies in "La Révolution Chimique." His contention there was that by every legitimate canon the experiment of June 24, 1783, gives to Lavoisier the priority of discovery. He now admits that Cavendish played "un rôle capital—car il donna le branle aux esprits vers la solution définitive." But how was this possible when Cavendish's memoir was not published until January 1784? There is really only one answer—it was given simply by the intervention of Blagden. I repeat that Blagden told Lavoisier of Cavendish's researches and of his conclusions, and that it was in the light of that knowledge that the experiment of June 24, 1783, was made. There can be no question of this. Blagden's testimony, as given in the letter to Crell, is as direct and decisive as it is damning. It was never contradicted by Lavoisier, nor by Laplace, Vandermonde, Fourcroy, Meusnier, or Legendre, who were present on the occasion when Lavoisier himself admits that he received the information.

M. Berthelot does not contradict it, but, instead, he asperses the moral character of Blagden. This method of treating a witness whose evidence cannot be rebutted is apt, when unsuccessful, to recoil on him who attempts it. It is perfectly true that Blagden interpolated the famous passage in Cavendish's memoir:—

"During the last summer, also, a friend of mine gave some account of them [the experiments] to M. Lavoisier, as well as of the conclusion drawn from them. . . . But at that time so far was M. Lavoisier from thinking any such opinion warranted that, till he was prevailed upon to repeat the experiment himself, he found some difficulty in believing that nearly the whole of the two airs could be converted into water."

This passage, however, was inserted with Cavendish's knowledge and consent, and by his assistant and amanuensis, who happened to be the very man who had a personal knowledge of the facts. Assuming the statement to be true, where is the immorality of the proceeding?

Everything that we can learn authoritatively concerning Blagden goes to show that he was an upright and honourable man. Sir Joseph Banks has testified to his abilities and integrity. Dr. Johnson spoke of his copiousness and precision of communication, with the characteristic addition: "Blagden, sir, is a delightful fellow." Laplace, Cuvier, Berthollet, and Benjamin Delessert, were among his friends.[1] He was rich, and was understood to have speculated to profit in the French funds. For thirteen years he was a Secretary of the Royal Society, and in 1792 he was knighted for his services to science. Every year he spent a considerable time on the Continent, and was frequently in Paris. The gossip of the period states that he aspired to the hand of Madame Lavoisier, who preferred Count Rumford. He died in Berthollet's house at Arcueil, on March 26, 1820. In an obituary notice in the *Moniteur* of September 22, 1820, M. Jomard testifies to his benevolence and generosity, and states that "none of his countrymen have done more justice to the labours and discoveries of the French, or have contributed more than he to the happy relations which have subsisted for six years (1814–20) between the *savans* of the two countries." By his will he provided liberally for his scientific friends: Berthollet, the daughter of Madame Cuvier, and the daughter of Count Rumford, each received £1000; and Laplace £100, "to purchase a ring." M. Berthelot asperses the character, not only of Blagden, but also of his countrymen by his insinuations. Would he have us believe that men like Berthollet, Cuvier, and Laplace, would extend their friendship to, and receive pecuniary benefits from, one whom they believed had foully stabbed their compatriot in the back? It is surely incumbent on M. Berthelot, on every ground, either to substantiate his implications or to withdraw them.

M. Berthelot makes the gratuitous assumption that I am ignorant of the work of Monge. Whether I am or not is altogether beside the mark. There is, indeed, no question of Monge. Monge distinctly disclaims priority to Cavendish, nor did he attempt to establish a right to be considered an independent discoverer of the true nature of water. In his memoir, "Sur le Résultat de l'Inflammation du Gas inflammable et de l'Air dephlogistiqué dans les Vaisseaux Clos," he tells us that the experiments recorded in it were made in June and July 1783, and repeated in October of the same year. "I did not then know," he adds, "that Mr. Cavendish had made them several months before in England, though on a smaller scale; nor that MM. Lavoisier and Laplace had made them about the same time at Paris in an apparatus which did not admit of as much precision as the one which I employed." I fail to see what M. Berthelot gains by his reference to Monge.

M. Berthelot reproaches Priestley and Cavendish for their adherence to phlogistonism. I say it with all respect, but is it seemly for M. Berthelot, of all men, to cast this stone? Is not he himself an exemplification of that conservatism which he deplores? A generation ago the doctrine of Avogadro became the corner-stone of that edifice of which M. Berthelot asserts that Lavoisier laid the foundations. Indeed, the introduction of that doctrine effected a revolution hardly less momentous than that of which Lavoisier was the leader. But what has been M. Berthelot's consistent attitude towards this teaching? We can illustrate it by a single example. He is the sole teacher in Europe of any position who continues to symbolize the constitution of that very substance of which he claims that Lavoisier discovered the composition by a formula which is as obsolete as any conception of phlogistonism.

T. E. THORPE.

[1] Many of the letters of Berthollet to Blagden are still in existence. In one of these, dated "19 Mars, 1785," he writes from Paris:—"L'on s'est beaucoup occupé ici ces derniers tems de la belle découverte de Mr. Cavendish, sur la composition de l'eau: Mr. Lavoisier a tâché de porter sur cet objet toute l'exactitude dont il est susceptible. . . . Mr. Lavoisier veut repéter l'expérience en faisant brûler l'air dephlogistiqué dans le gas inflammable, et il y a apparence qu'alors on n'aura point d'acide nitreux, sel n les belles observations de Mr. Cavendish." Is this language consistent with the belief that Berthollet, who must have known the facts, regarded Lavoisier as the real discoverer of the compound nature of water?

A HAND-BOOK OF PHOTOGRAPHY.

Handbuch der Photographie. Part I. Fourth Edition. By Prof. Dr. H. W. Vogel. (Berlin: Robert Oppenheim, 1890.)

THIS is the latest edition of a work which has been known in Germany for ten years, and of which the author is the Director of the Photochemical Laboratory of the Imperial Technical High School in Berlin. The existence of such a post as that occupied by Dr. Vogel in one of the foremost technical schools of Germany is as much an indication of the advanced state of technical education in that country as the non-existence of such specialists in the technical schools of this country is a sign of our comparatively backward condition in the field of chemical technology. The subjects comprised under this heading are so wide in their range and so difficult to grasp, excepting by actual personal contact with the chemical industries, that no instruction likely to be of any great value to those preparing for, or engaged in, the latter can be given, unless the instructor has this qualification. Nor can the student properly avail himself of the instruction thus offered, unless he on his part is well grounded in the general principles of the science which underlies his subject. When such a ground-work has been laid, and the student thus equipped is passed on to the specialist, the result is a chemical technologist who is likely to be of real use to his country. The Germans have realized this long ago—the machinery exists both for laying the foundation and for raising the superstructure of specialized knowledge. In this country, so far as chemical technology is concerned, we have not yet advanced very much beyond the stage of furnishing the appliances for the general training—the real technical or special training has been allowed to take care of itself, and the student is supposed to have finished his education at the time when he ought really to be beginning it.

These ideas naturally suggest themselves in having brought under one's notice the various special works on applied science which reach us from time to time from the German press, and of which Dr. Vogel's book is a not unfavourable specimen. The present volume, which is the first part of the work only, contains some 350 pages, and the advancement of the subject since the last edition is indicated by the fact, which the author states in the preface, that the subject of photochemistry alone has been increased from 8½ to 22 pages. The whole volume consists of an introductory portion, three chapters, and an appendix. We propose to give, in the first place, a brief analysis of its contents.

The introduction consists of a history of photography, followed by some remarks on the study of the subject. The scientific aspect of photography forms the subject of the three chapters which constitute the main portion of the work. The first chapter deals with the physical action of light, and comprises such subjects as phosphorescence, phosphorography, the photophone, telephotography, the action of light on polished surfaces, Crookes's radiometer, and the action of light on ebonite, including an account of Edison's tasimeter, which, the author thinks, may become serviceable as a chemical photometer.

The second chapter occupies over 200 pages, and is divided into two sections, dealing with the action of light on non-metals and metals respectively. The subdivisions of this portion of the subject are well planned, but are not carried out with logical consistency. The action of light on inorganic compounds brings in allotropy and the photochemical combination of hydrogen and chlorine, &c. The action of light on organic compounds begins with the remarkable subject of the photopolymerisation of such compounds as vinyl bromide, anthracene, quinine, chloral, and asphalte, the latter, of course, leading to the original heliographic process of the elder Niepce. The author gives good reasons for the belief that the change in this last case is due to polymerisation, and not to oxidation. Instances of combination between organic compounds under the influence of light are then discussed, the formation of a compound from phenanthrenequinone and acetaldehyde being compared with the synthetical processes which go on in plants by the action of this same agency.

The photochemical decomposition of organic substances is dealt with at considerable length. The remarks concerning the action of light on cellulose in the form of wood and paper should be carefully studied by those interested in the technology of paper-making. The action of light on colouring-matters, both organic and mineral, is also treated of very completely, and the tables given will be found valuable to dyers, colourists, and painters. This portion of the subject is covered to some extent by Russell and Abney's Report on the fading of water-colours, of which the author has evidently availed himself. With respect to the fading of organic colouring-matters, it is of interest to note that all the artificial yellows are faster than the natural vegetable yellows. The section treating of the action of light on the vital processes of plants and animals brings the author into contact with such physiological subjects as germination, the formation of chlorophyll and other plant colouring-matters, the respiration of plants, and Aimé Girard's observations on the formation of sugar in the beetroot. Under the action of light on animals, the author gives an account of Engelmann's experiments on *Bacterium photometricum*, but Lubbock's analogous experiments with the Daphnidæ are not alluded to.

Passing to the second section, we find 167 pages devoted to the action of light on metallic compounds. The logical sequence is here broken by the introduction of a large amount of ordinary chemistry, *i.e.* the formulæ and properties of the most important compounds of the metals used in photography. This is very well in its way, and it is essential that the scientific photographer should be familiar with this portion of his subject, but it may be suggested that in future editions these paragraphs should be relegated to the third chapter, which deals with the chemistry of photographic materials. The author's use of formulæ, we may here point out, is somewhat antiquated, capricious, and inconsistent. Thus in some places chloracetic acid is written $C_2\left.\begin{matrix}H_3\\Cl\end{matrix}\right\}O_2$, ferrous tartrate, $C_4\left.\begin{matrix}H_4\\Fe\end{matrix}\right\}O_6$, ferric tartrate, $C_{12}\left(\begin{matrix}H_{12}\\Fe_2\end{matrix}\right)O_{18}$, ferrous acetate, $C_4\left.\begin{matrix}H_6\\Fe\end{matrix}\right\}O_4$; while on the same page, or in other parts of the book, we find ferric citrate written, $(C_6H_5O_7)_2Fe_2$, silver tartrate, $C_4H_4O_6Ag_2$, and silver citrate, $C_6H_6O_7Ag_2$. In the same equation, on p. 152, sodium thiosulphate is written $Na_2S_2O_3$, and the double silver salt, $\left.\begin{matrix}Na_4\\Ag_2\end{matrix}\right\}3S_2O_3$. Then, again, some compounds of very definite composition, such as sodium nitroprusside, Prussian blue, &c., are not favoured with formulæ at all; while in other cases, such as under the salts of ammonia, the alkalies, and the alkaline earths (third chapter), the formulæ suddenly rise to the dignity of thick type.

Under the action of light on iron salts, we have a description of the various printing processes depending on the use of these compounds, such as Willis's platinotype, the negative and positive blue processes and other less widely-known methods. Under chromium compounds we have an account of the chromatized gelatine processes, including that of Pretzsch (relief process), Fox Talbot (steel etching), pigment printing, Woodburytype, photogalvanography, lithography, and zincography, and a multitude of other processes, which form quite a special feature among the recent developments of applied photography. The salts of uranium and copper are dealt with in due order, but the chief interest, of course, centres in the compounds of silver. After a brief description of the pulverulent metal, the use of silver as a developing agent in acid and alkaline developers is discussed. Speaking of the black compound which is precipitated when ammonia is added to a solution containing silver nitrate and a ferrous salt, the author uncompromisingly gives the formula, $Ag_4O + Fe_3O_4$, which at least may be said to require confirmation. The chemical principles of intensification and toning, and the transformations of silver pictures by substitution, are well dealt with, and a long account of Carey Lea's researches on the allotropic modifications of silver is given. When treating of silver nitrate, Dr. Vogel gives way to patriotic bias in the form of a footnote:—

"Als Thatsache erwähnen wir, dass das in Deutschland fabricirte Silbernitrat das reinste ist, welches geliefert wird. Ueberhaupt übertreffen ALLE deutschen Chemikalien die ausländischen weit und werden daher von allen Pharmazeuten des Auslandes hoch geschätzt. Selbst in China, Japan, Indien, Nordamerika werden deutsche Chemikalien allen übrigen vorgezogen. Wenn zuweilen in ausländischen Zeitungen Verdächtigungen derselben versucht werden, so laufen diese auf Concurrenzneid hinaus" (p. 147).

Our chemical manufacturers had better see to this!

Of fundamental importance in photography are the silver haloids, and to these we naturally turn with the greatest interest. The author admits the existence of a subchloride, but justly expresses reserve as to its formula. The "photosalts" of Carey Lea are described, and the oxychloride theory referred to, but the author omits to mention that these coloured compounds, produced by chemical methods, were discovered by the British Association Committee of 1859. Photochromy is treated of briefly, and in an earlier portion of the work (p. 9) the author distinctly asserts that permanent photography in natural colours has never been accomplished. Of course we knew this before, but it is well that the public should have the statement from such a recognized expert as Dr. Vogel. Under silver bromide will be found an account of Stas's modifications of this haloid, and after discussing the ripening of the salt in emulsions, and the action of ammonia thereon, the author arrives at the conclusion that these modifications represent different states of physical aggregation—a conclusion which most scientific photographers will endorse. The discussion of this part of the subject is, we may add, very thorough. Silver iodide is similarly treated of, and then comes a section on the influence of different substances on the sensitiveness of the silver haloids.

This last subject leads to the action of sensitizers, and some very useful tables, giving the results of experiments with all kinds of sensitizers, are here given. The subject of development, which the author divides into chemical and physical, is dealt with under this same section, and the different compounds which have been used for this purpose are enumerated. Sensitizers are again discussed after development has been disposed of, and we are sorry to see that Dr. Vogel still classifies these as chemical and optical sensitizers. The latter comprise those colouring-matters which confer on the silver haloid film a special sensitiveness for certain rays of low refrangibility, and the author gives a long account of this discovery, with which his name will always be associated. We confess to being somewhat disappointed with this section. The theory of orthochromatic photography is in a very unsatisfactory state, and we should have liked to know the author's views on this subject. By his still retaining the term "optical sensitizer," he leads us to infer that he has not abandoned the physical theory. In this case a discussion of Abney's results and a repetition of his experiments are most urgently needed. We shall, however, perhaps, be more enlightened in the practical portion of the work which is to follow the present part.

In reviewing the history of orthochromatic photography, the results of Eder are given almost *in extenso*, but the experiments of Abney and Bothamley in connection with this subject are not referred to. Perhaps these, again, are being reserved for the succeeding parts of the book. Dr. Vogel can certainly score against those who discredited his discovery in 1874, but he is hardly correct in stating that the Berlin Academy of Sciences alone recognized its importance. In NATURE, vol. x. p. 281, the value of the discovery was pointed out, and an account, of the early experiments was given. The treatment of the subject of solarisation, which follows that of "optical sensitizers," is somewhat meagre, and from the scientific point of view we should have been glad to have a more complete discussion of a topic of such fundamental importance to the theory of the photographic image. The author accepts the explanation of reversed chemical action, but he does not, we venture to think, lay sufficient stress on the important part played by the vehicle or sensitizer in this phenomenon.

After dealing with the salts of silver, we are led in due order to the compounds of mercury, lead, gold, platinum, and allied metals. The only comment we have to make is that the ordinary chemical properties of these different salts would be more in place if described in the third chapter, so that this portion of the work might be restricted to what its title indicates, viz. the chemical action of light. Nor do we understand why the author should retain the old name "platina," as his own countrymen have now generally dropped the terminal letter, while here and in America the names of all the metals of the group are made to end in "um." It certainly seems strange to a chemist of the present time to read: "hierher gehören Platina, Iridium, Palladium, Osmium, &c."

The third chapter is devoted to a description of photographic chemicals, and is more or less of the nature of an ordinary descriptive manual of chemistry, having special reference to the elements and compounds used in photography. Among the metalloids, oxygen, hydrogen, and the halogens are alone treated of. Under solvents, we have the compounds water, ethyl and methyl alcohols and some of their homologues, glycerin, ether, chloroform, benzene, &c. Then follow the acids, inorganic and organic, and bases and salts, beginning with the compounds of potassium, sodium, and ammonium, and ending with those of the earthy metals. The salts of the heavy metals, having been taken (out of order) in the preceding chapter, are not dealt with here. The author, in explaining the theory of salts, clings to the old water type, *e.g.* $\left.\begin{matrix}SO_2\\H_2\end{matrix}\right\}O_2$, $\left.\begin{matrix}NO_2\\H\end{matrix}\right\}O$, &c. Under ammonia (p. 269) we are told that in the salts of this base ammonium (NH_4) is present, "das mit Sauerstoff das Ammoniumoxyd (NH_4O) bildet." On p. 261 potash alum is written $K_2SO_4 \cdot Al_2(SO_4)_3 + 24H_2O$, and on p. 269 ammonia alum is formulated $(NH_4)Al(SO_4)_2 + 12H_2O$. The section on reducing agents and developers treats of hydroxylamine, tannin, gallic acid, pyrogallol, hydroquinone, pyrocatechol and resorcinol, paraphenylene-diamine, phenylhydrazine, and eikonogen.

Following this section we again have some ten pages devoted to optical sensitizers, the compounds described being eosin and allied colouring-matters, cyanin, quinoline red, and chlorophyll. There are some amusing footnotes attached to this section, one of which we cannot refrain from quoting, as illustrating the author's method of dealing with the sceptics at home and abroad. After attempting once more to make clear his definition of an optical sensitizer, he admits that this definition can only be made intelligible to those

"welche von farbigen Strahlen, d. h. Spectralfarben, und von optischer Absorption derselben, also Absorptionsspectralanalyse, eine klare Vorstellung besitzen, die leider bei sehr vielen Empirikern (und auch Wissenschaftern) die in dieser Sphäre arbeiten, vermisst wird."

Then comes the note :—

"Wie übel es in dieser Hinsicht bestellt ist, geht daraus hervor, dass sogar ein Professor der Chemie und Physik in Berlin das Spectrum von Eosin und Eosinsilber, welche total von einander verschieden sind, als gleich erklärte, dass der gerichtliche Sachverständige Prof. Spiller in England die Behauptung aufstellte, Eosin und Chinolinroth seien identisch, und dass sogar Carey Lea meinte, ein Sonnenspectrum lasse sich durch eine Anzahl farbiger Glasstreifen ersetzen."

We do not regard it as "good form" in this country to make horrid examples of our co-workers in a book intended for the use of students. If any remarks of a polemical character had to be brought forward, there were other arenas, both here and in Germany, where Dr. Vogel might have broken a lance with his adversaries.

Under the heading "Bildträger" (image-carriers or film-producing materials), we have an account of cellulose, starch, pyroxylin, albumin, gelatine, and paper. The description of the various cellulose nitrates and their preparation is fairly complete. Under gelatine we do not find, either in this chapter or in the historical portion, any reference to the name of Maddox, who first made the use of this vehicle practicable, and laid the foundation of our modern gelatino-bromide emulsion processes. Some miscellaneous subjects which are not included in the text are added in an appendix. It must be mentioned that there are numerous prints and thirteen plates inserted in the work, some of them very beautifully executed, and introduced with the object of illustrating the various photo-etching, engraving, and printing processes, the difference between orthochromatic and ordinary plates, spectrum photography on dyed films, &c.

With respect to the work as a whole, it will be seen that it covers to a large extent the same ground as the "Ausführliches Handbuch der Photographie" of Eder, which is also a recognized standard work. In some respects Dr. Vogel's book offers advantages over the latter, but in other respects it is inferior. We miss the splendidly complete lists of references with which Eder's work abounds, and in neglecting to supply this information the author often unconsciously does himself injustice, for there is much original work included in the volume which many readers would desire to refer to in the original papers. Dr. Vogel has contributed so largely to the advancement of photography that any observation or experiment of his is entitled to the fullest consideration.

The criticisms which have been offered in the course of this notice are on minor points, but taken in their *ensemble* they indicate certain weaknesses which are to be regretted. It is obvious from the examples given that pure chemistry is not the author's strong point, and it would have been better, seeing how largely the subject is connected with this science, if he had consulted some of his chemical colleagues. The inconsistencies of formulation and classification which have been pointed out might thus have been avoided, and the work made more logically coherent. Another defect is the retention here and there of passages which look like survivals from an earlier edition. For example, we read on p. 7: "Der Collodium process verbreitete sich allgemein, wurde im Laufe der Zeit immer mehr und mehr vervollkommnet und ist jetzt der ausschliesslich angewendete." Again, on the same page: "Collodium für den Negativprocess, Albuminpapier für den Positivprocess bildeten die wichtigsten Grundlagen unserer photographischen Bilder." This may have been true at the time of the last edition (1878), but is certainly not the case now.

In concluding this notice we can only express regret that the author should have fallen into the habit, now, unfortunately, becoming only too common on the Continent and across the Atlantic, of allowing insufficient credit for, or, worse still, of ignoring altogether, work done outside his own country. The historical portion of the book hardly does justice to the labours of Fox Talbot when it is stated that "nach dem Bekanntwerden der Daguerre'schen Entdeckung suchte Talbot auch Camerabilder auf Papier aufzunehmen." If the introduction of the collodion process by Archer and Fry is considered worthy of historical record, surely the gelatino-bromide emulsion process of Maddox is at least of equal importance. When dealing with the action of light on selenium (p. 23), the author gives a description of Shelford Bidwell's experiments on telephotography, but the experiment of Ayrton and Perry having for its object the electrical transmission of moving images (*telopy*) is not referred to. When treating of optical sensitizers, he tells us that von Baeyer discovered fluoresceïn, that Caro discovered eosin, and that Jacobsen discovered quinoline red, but the reader is not informed that cyanin, one of the best special sensitizers, was given to science by Greville Williams as long ago as 1860. These and the other blemishes which we have felt bound to indicate have only to be remedied in future editions to make Dr. Vogel's book take that high position to which it is justly entitled, both on account of the vast body of useful and often original information which it contains, and the deserved reputation of the author as one of the foremost of German scientific photographers.

R. MELDOLA.

CONTRIBUTIONS TO INDIAN BOTANY.

Annals of the Royal Botanic Garden, Calcutta. Vol. II. Pp. 110; with 104 Lithographed Plates. (Calcutta: Bengal Secretariat Press, 1889.)

THE whole of this volume, like the first, with the exception of a part of the Appendix, is the work of Dr. G. King, the Director of the Calcutta Botanic Garden. It contains a monograph of the species of *Artocarpus* indigenous to British India, and a monograph of the Indo-Malayan species of *Quercus* and *Castanopsis*, both fully and excellently illustrated. The genus *Artocarpus* was founded by the Forsters (father and son, who accompanied Captain Cook on his second voyage, not brothers, as inadvertently stated by Dr. King) for the bread-fruit tree, with which they became familiar in the Pacific Islands. This they called *Artocarpus communis*, though most subsequent botanists have adopted the later Linnean name, *A. incisa*; and the younger Forster published a separate illustrated memoir on it, in German, entitled "The History and Description of the Bread-fruit Tree." Dampier, however, appears to have been the first to make this valuable tree known to Europeans. The only other familiar species of the genus is the Jak fruit (*Artocarpus integrifolia*), a prominent cultivated tree in the Malay peninsula and archipelago, and recently collected by Colonel Beddome in a wild state in the forests of the Western Ghats in the Deccan Peninsula, South India. Exclusive of this, Dr. King now describes and figures seventeen species found within the limits of British India, seven of which are described for the first time. Many of them are very handsome trees, but their wood is of little value, and, as far as their history goes, none yields an edible fruit.

The Indo-Malayan species of *Quercus* and *Castanopsis* number 82 and 22 respectively, besides some imperfectly-known species. As Dr. King remarks, there is no reason, except convenience and the desirability of not adding to the already overloaded synonymy, why all the species described under *Castanopsis* should not be placed in the section *Chlamydobalanus* of *Quercus*. Generally speaking, *Castanopsis* differs from *Quercus* in the involucre, which answers to the cup of the acorn, being prickly or tubercular, and completely inclosing the nut, and when ripe splitting irregularly to free the nut. But this distinction completely breaks down in the long series of species illustrated in the present monograph, the cup or involucre varying, in the species referred to *Quercus*, from two or three series of scales, or a discoid form, to an ovoid or globose receptacle completely enveloping the nut, and sometimes more or less prickly. In *Castanopsis*, on the other hand, the involucre is sometimes quite smooth. In foliage there is nothing to distinguish them, yet, taking the whole series of species, these Asiatic oaks exhibit a wonderful and beautiful variety in foliage and fruit, especially in the latter, being in many of them exceedingly elegant in shape and structure. There are about half-a-dozen species of the same group (*Lepidobalanus*) as the British oak, but none has quite the kind of foliage characteristic of this, and some have leaves more like an apple-tree, others almost exactly the same as the sweet chestnut. In other groups the leaves are often very large, thick, and leathery, having entire margins. Like some of the oaks of Central America, some of the Indian species have acorns of enormous size. One of the handsomest trees of the Eastern Himalayas, at elevations of 5000 to 8000 feet, is *Quercus lamellosa*. It grows from eighty to a hundred feet high, and in young vigorous specimens the conspicuously veined leaves are as much as a foot long, and the depressed spheroidal cups or involucres are 2½ inches in diameter, enveloping all but the apex of the nut, and built up of broad concentric plates, thin towards the usually fimbriate edge. The figures illustrating this species in Dr. King's monograph are partly copied from Hooker's "Illustrations of Himalayan Plants," though this fact is not mentioned, which is apparently an oversight, as all other copies that we have noticed are acknowledged. Running through the plates from the beginning, we will indicate a few of the more striking. Thus, *Quercus semecarpifolia* (Plate 15), has globose acorns with the cup reduced to a small disk at the base; *Q. serrata* (Plate 16) is remarkable for having the acorn almost buried in a cup of long narrow scales; *Q. oidocarpa* has an ovoid acorn with a closely-fitting cup, at least two-thirds of its length, and consisting of a few elegantly notched broad plates; *Q. Kunstleri* (Plate 31) has the long narrow acorns in spikes, and seated in shallow cups similar to those of the common oak; *Q. grandifrons* (Plate 35), has broad leaves sometimes 15 to 18 inches long, and *Q. Scortechinii*, on the same plate, has a mossy cup containing a huge obovoid acorn; *Q. platycarpa* (Plate 65) has very flat acorns half immersed in the thin cup, and about an inch and a half across; *Q. cyclophora* (Plate 67) is somewhat similar, but the cup is very thick, and composed of very numerous rounded scales; in *Q. reflexa* (Plate 72) the cone-shaped acorns are borne in clusters, and entirely inclosed in a thin cup completely beset with short recurved prickles; *Q. Junghunii* (Plate 73) is so like a *Castanopsis* in its unsymmetrical prickly fruit as to be undistinguishable from it; and, finally, *Q. Beccariana* (Plate 78) presents a fruit more resembling the nest of a solitary wasp than an acorn, being an oblong body about three inches long by two broad, the cup entirely inclosing the acorn, and consisting of about four very broad overlapping layers of scales with thin edges.

Apart from the practical use of Dr. King's monograph, this long series of figures of the Indian oaks offers a most interesting opportunity to the student of evolution, especially if it be remembered that the figures are portraits of individual specimens, not embodiments of "species," and that another series of specimens of the same "species" would probably exhibit many intermediate modifications.

It is fortunate for science that Dr. King, supported by the Indian Government, should devote his time and talents to the elucidation of such large and difficult arboreous genera as *Ficus* and *Quercus*. These monographs are of the greatest value to botanists generally, and one would say specially valuable to the officers of the Forest Department of India. The drawings by native artists, are, as already stated, with few exceptions, original, very faithfully executed, and mostly sufficient for purposes of identification. The lithography, too, by the Government School of Art, Calcutta, deserves praise, comparing favourably with much of the work done in this country. We may perhaps be permitted to call attention to the fact that the copies we have seen of the present volume are printed on smaller paper than the first, which detracts from their appearance on the shelves.

W. BOTTING HEMSLEY.

OUR BOOK SHELF.

Elementary Text-book of Trigonometry. By R. H. Pinkerton, M.A. New Edition. (London: Blackie and Son, Limited, 1890.)

THIS is a new and enlarged edition of this excellent elementary text-book. An account of the method of proportional parts and of its application to logarithmic and trigonometrical tables has been added, together with a collection of questions in trigonometry which have been set during the last ten years in examination papers of the Science and Art Department in mathematics, second stage, and of the London University Intermediate Examination in Arts.

Instead of each paper being given separately, the questions in them are arranged under headings, and the source from which each is taken is indicated; and, to avoid the necessity of a book of tables, the logarithms required for their solution are given in a table at the end.

Throughout the work the author has explained most clearly and fully every part that might in any way prove difficult to the beginner, and he has added numerous well-chosen examples at the conclusion of each chapter.

Higher Geometry. Containing an Introduction to Modern Geometry and Elementary Geometrical Conics. By W. J. Macdonald, M.A. (Edinburgh: James Thin, 1890.)

Many of the more advanced theorems in geometry, which are not very often treated to any extent in elementary books, are here dealt with. The author's idea seems to have been to connect the theorems together as much as possible in a continuous and graduated series; and this, together with the fact that they are worked out in a neat and concise form, will greatly add to the utility of the book.

The latter part of the work treats of geometrical conics. Although it does not contain so many propositions as many of the elementary works on the subject, yet the author has included in it all the most important propositions, thus making it a brief course for those who are about to attack the subject for the first time. Many problems have been put in here and there among the propositions, and an index to definitions, which has been added at the end, ought to prove handy for reference.

Nautical Surveying. By the late Vice-Admiral Shortland, LL.D. (London: Macmillan and Co., 1890.)

This volume, which is published by the late Admiral's widow and children, relates chiefly to the errors to which surveyors and their instruments are liable. It shows how these errors are to be found and corrected. The book is not one for beginners, but appears to have been written rather for surveyors themselves, after they have become thoroughly acquainted with the more practical and simple surveying. Every branch of surveying is thoroughly discussed, but at such length that the work would be of little practical use to a beginner. An index would greatly improve the book.

An American Geological Railway Guide. By James Macfarlane, Ph.D. Second Edition. (New York: D. Appleton and Co., 1890.)

The first edition of this book appeared in 1878, and the object of the compiler was to provide travellers with a hand-book from which they might learn the geological structure of every district in America intersected by railways. Many changes and additions have, of course, become necessary since 1878; and at the time of his death, in 1885, Dr. Macfarlane had made extensive preparations for a new edition. His work has been completed by his son, Mr. James R. Macfarlane, who has had the advantage of being aided by various competent contributors and advisers. The idea of the book is excellent, and has been carried out with great care and intelligence. It relates to the Dominion of Canada, as well as to the United States, and anyone travelling in these countries may find out at once, by turning to the proper page of this volume, the geological significance of phenomena that may happen to attract attention during the journey. The work ought to do much to encourage a liking for geology in the New World; and even professional geologists may find it useful for occasional reference.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Araucaria Cones.

I should be glad to know through any of your correspondents whether the Araucaria is often known to bear cones in the British Islands?

A plant of the common Araucaria in my garden here was blown down in a severe gale two years ago. It was a well-grown plant about 20 feet high, and very healthy. I replaced it on the spot, supporting it by ropes well pinned down.

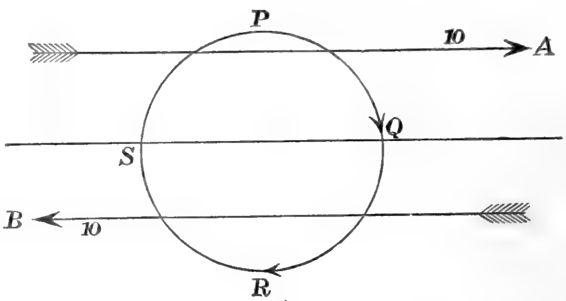
This autumn it has come out covered with cones all over the top branches. I have never seen them before, and I think they must be rare. They are terminal on the branches which bear them—sit upright upon them—and are of a very handsome ovate form. No scales are visible—the actual seed-vessels being covered and concealed by a thick coating of modified leaves or needles, narrowed, elongated, and terminating in hooked bristles.

Argyll.

Inveraray.

On the Soaring of Birds.

It is a pity that so many of your correspondents on this subject fail to grasp the elementary and self-evident fact that no common horizontal movement, relatively to the surface of the earth, of the air in which a bird is immersed can by any possibility enable it to soar. Upward convection-currents and upward slants may have something to do with the question, as may also the existence of different horizontal currents.



Thus, let there be two horizontal currents, A and B, in opposite directions, of 10 miles an hour each, and let a bird arrive at Q, down the path PQ, moving through the air at Q with a velocity of 5 miles an hour. On passing into the current B, it has a velocity relative to B of 20 miles an hour in the direction of current A, and of 5 miles an hour in a perpendicular direction. By proper adjustment of the wings, this relative velocity can be converted into work, and spent in lifting the bird to a higher altitude, so that, on arriving at S, its velocity relatively to the A current is again reduced to 5 miles an hour, and the circumstances at Q are exactly reproduced. When Mr. Magnus Blix began his communication (August 21, vol. xlii. p. 397) I expected that he was going to suggest this explanation; but though he commences with the supposition of the bird passing from one current to another, he goes on as if the bird afterwards remained constantly in one current.

An upward convection-current, as suggested by Mr. O. Fisher (September 4, p. 457), is, no doubt, a *vera causa* for a bird's being assisted in floating; but has Mr. Fisher reflected or calculated whether it is an adequate cause for actual soaring? Natural convection-currents can seldom have a rate of more than a few feet per second, whereas a velocity of 20 feet per second would be required to support a bird which weighed 1 pound for every square foot of supporting surface—wing, tail, and body. It is true that, in soaring, the rapid horizontal motion probably increases the horizontal support of the air, just as the transverse motion of the sails of a windmill through the air-current propelling them increases the horizontal pressure, as is proved by the fact that windmills evolve more work than they would be calculated to evolve if the pressure were the same as when they are at rest. The great difficulty, however, in all these explanations is that birds soar under circumstances which render these explanations inapplicable. In the open ocean, where a steady wind is blowing, where there are certainly no upward convection-currents, and where, equally certainly, there are no cross currents or diverse horizontal currents, where from the smoke of the steamer it is obvious that the air is moving *quasi* rigidly—that is, without perceptible internal motion—birds nevertheless soar to perfection.

As definite instances, however, are of more value than abstract statements, I subjoin copy of an actual observation made by myself and a friend some years ago. As the eyes become tired and dazzled in following the same object intently, we took it in turns to watch the bird, exchanging watch when the bird was so situated as to be easily identified.

"*Walmer Castle*, May 4, 1876" (on voyage home from the Cape).—"Observed a common gull for 11 minutes by the watch, following the ship without flapping a wing. The wings were used occasionally, but with a slow motion, as if for balancing or changing direction. The tail was occasionally altered in position when the bird ascended or descended.

"During the time of observation, the bird sometimes followed the ship with a steady motion, without apparently changing its height or velocity. Occasionally it veered to right or left a distance of a hundred yards or so, it rose and fell in altitude, changed its direction, fell back or overtook the vessel, without any apparent muscular effort. In overtaking the ship it seemed rather to rise than to fall" (though this is very difficult to judge of, because one cannot allow with any exactness for perspective or parallactic change of position).

"The direction of the wind, relatively to the ship, was E. by N., its velocity, as estimated by Captain Webster, was 7. The course of the ship was N.E. ½ N., its rate 8 knots.

"While following the ship, the bird was often within 15 yards, at which time there was no perceptible inequality in the horizontal angles of its wings, and no perceptible angle made by the axis of its body with the ship's keel.

"In moving to right or left out of the ship's course, there was generally a change of level." F. GUTHRIE.

South African College, Cape Town.

The Value of Attractive Characters to Fungi.

THE importance of attractive colours and odours and of modifications of form to flowering plants is now perfectly understood; but the value of attractive characters to fungi has received comparatively little recognition. At first sight it would seem unnecessary that a plant, insusceptible of fertilization, should possess characters apparently designed to enlist living creatures in its service: there is no pollen for them to carry, and no ripe seeds for them to distribute, and yet attractive characters, such as colour, taste, and odour, are extremely well marked.

The colours which fungi exhibit include almost every hue from white to black. We have the brilliant red of the Peziza cups; the orange-scarlet of the *Amanita muscarius*, with its cap gaily speckled with white; the crimson of the *Russula emetica*; the rich yellow of the *Cantharellus cibarius*; the blue of the bruised *Boletus luridus*; the amethyst of the *Agaricus laccatus*; and the dark green of the bruised *Lactarius deliciosus*, with every possible shade to the deepest jet. But not only have fungi colours that are attractive by day; some, like the *Agaricus olearius*, are phosphorescent by night. Many tropical species light up the jungle in the hours of darkness; and in this country the coal-mines are often found illuminated by one of the polypores which propagates itself on the timbers of the workings.

The tastes and odours of fungi are equally varied and attractive. Many Agarics have an odour of fresh meal; the *Hydnum repandum* rejoices in the flavour of oysters; the *Armillaria mucidus* in that of nuts; the yellow Chanterelle in that of apricots; others have the scents of various flowers, such as the violet and woodruff; or of aromatics like anise; while a large number have an indescribable damp cellar or fungus smell, such as slugs delight in. Many, like the shameless stinkhorn, *Phallus impudicus*, emit an intolerable stench which so strongly resembles

"the carrion of some woodland thing"

that blow-flies and ravens quickly find it out.

There can be little doubt that these are attractive characters. What, then, can be the service which these characters induce animals to perform for fungi? To answer this let us review briefly the life-history of any fungus possessing characters of an attractive kind.

The common mushroom, *Psalliota campestris*, is particularly agreeable to sheep and oxen, and is abundant in autumn in rich pastures. Although there is still much in our knowledge of its life-history that is incomplete, yet it is evidently composed of two main periods: first, a parasitic period passed in the body of an animal host; and secondly, a saprophytic period passed on some suitable organic soil. Let us sow the spores of a ripe mushroom as carefully as we may, none of them will grow: the first stage of the mushroom's existence must be passed in the body of an animal host; and as horses, sheep, and oxen are all readily attracted by its taste and mealy smell, it has never any difficulty in finding a host to take it in.

When once the spores have passed from the body of the host, they produce a mycelium, from which the future mushroom is formed. The connection between fungi and animal droppings is a matter of very early observation, and our forefathers were wont to believe that certain evil species came from the body of the Wicked One, and familiarly called them Tode's-stools, or Devil's droppings.

In this division of the life-history of fungi I believe we have the key to the value of attractive characters. Horses, oxen, sheep, foxes, squirrels, moles, birds, snails, and insects are all attracted by appropriate scents, tastes, and colours; and the forms and habitats of fungi are those which have best succeeded in attracting their particular hosts. There is no living being either great enough or small enough to escape the attentions of these plants in their ceaseless endeavours to attract; and among fungi, just as among flowering plants, every variation of form, scent, and colour has been perpetuated and developed, because it has been successful in attracting and in thus securing the multiplication of the species.

The subject is one, I think, that requires the gathering together of much individual observation in all parts of the world; and it would be well if those who have the opportunity would note at the time the name of the fungus and its observed host, and if students of biology who possess facilities for laboratory work would follow the matter still further by artificial cultures, and so determine the changes that take place in the body of the host, and the course of the alternating sexual and agamous generations. CHARLES R. STRATON.

Wilton, Salisbury.

Extraordinary Flight of Leaves.

MR. SHAW'S letter (NATURE, vol. xlii. p. 637) is a curiously corroborative fact in support of Mr. Wallace's theory of the wind being an agent for the dispersion of seeds, which he so strongly urges in his book, "Darwinism," to account for the universal distribution of many plants. For if, as the letter intimates, such weighty objects as oak-leaves can be conveyed through the air in such vast numbers as to cover an area two miles long by one in width, then it would not require a wide stretch of imagination to conceive that miniature objects like seeds, delicately winged for flight by Nature as so many are, might travel by thousands for hundreds of miles in favourable winds.

Speaking of leaves, on the morning of that severe frost last week, I observed a horse-chestnut, in full foliage, showering down its leaves with extraordinary rapidity, so that in three hours the tree was bare—half the leaves were yellow, the rest still quite green. The gardener gathered twelve large barrow-loads from beneath it. R. HAIG THOMAS.

November 1.

Kœnig's Superior Beats.

THE interesting experiments of Dr. Kœnig at the meeting of the Physical Society on May 16, and described in NATURE (vol. xlii. p. 190), have induced me to offer your readers the following view of Dr. Kœnig's superior beats and beat-tones.

If we look for the physical cause of the superior beats, we find nothing but the inferior beats themselves to build upon. But if we can admit that inferior beats may be in an ascending and descending scale of intensities, we have at once the structure of a beat which may be appropriately termed a superior beat, viz. the beat resulting from the periodic recurrence of a maximum and minimum inferior beat, in the same manner as the inferior beat is the result of the periodic recurrence of a maximum and minimum vibration.

Now, all inferior beats can be divided into two classes—similar and dissimilar beats. The four beats given by 128 vibrations, with 124 vibrations in the second, are perfectly similar beats, because the ratio $\frac{128}{124}$ is $\frac{4 \times 32}{4 \times 31}$, *i.e.* the ratio in its simplest form is $\frac{32}{31}$, giving one beat under precisely the same conditions of phase coincidence, at each quarter of a second. But the four beats given by 127 vibrations, with 123 in the second, are dissimilar beats; because the two S.H.M.'s, though together four times in the same phase in the second, these coincidences are at different parts of the wave-length; just as the hands of a watch are twelve times together in one complete revolution of the hour hand, but at different parts of the dial.

Another example will complete my meaning. The example is an experiment described by Dr. Kœnig in his valuable work, "Expériences d'Acoustique," with the two tuning-forks making 75 and 40 vibrations in the second, English measure. Five distinct beats were heard along with the beat-sound of 35 beats in the second. Here we have the interval-ratio $\frac{75}{40} = \frac{5 \times 15}{5 \times 8}$ showing (15 – 8) or 7 dissimilar beats recurring five times in the second. And we have apparently no other physical quantities to deal with. So that it appears a necessary conclusion that the seven dissimilar beats are in an undulatory order of intensity, in order to account for the five superior beats of Dr. Kœnig. The construction is then simple. Each recurrence of the 7 dissimilar beats is marked by a beat, and there are 5 of these in the second. These are the 5 superior beats formed out of the 5 × 7, or 35 inferior beats.

For this reason I have introduced the term cycle for the resultant generating curve formed by two S.H.M.'s of unequal periodic times. The curve or cycle is traced by the extremity of one generating radius revolving about the moving extremity of the other as a centre, and is complete when the two radii return to their original position. The cycle may be of long or short period. In the octave interval it is very short. With a nearly perfect unison it is very long. In every cycle there is at least one beat. There may be many dissimilar beats, but there cannot be any similar beats in the same cycle. The superior beat, number is, then, the number of cycles in the second; and the inferior beat-number is the product of the number of cycles into the number of dissimilar beats in the cycle.

According to this theory, therefore, the superior beats heard on the occasion referred to should be accounted for as follows:—

(1) When the two tuning-forks were executing 120 and 64 vibrations respectively in the second, eight superior beats were heard, because $\frac{120}{64} = \frac{8 \times 15}{8 \times 8}$ gives 8 cycles of 7 dissimilar beats, in each second of time.

(2) When the forks were making 96 and 64 vibrations, or the fifth interval, 3/2, it would be more correct to say that there were no superior beats than to say that "the inferior and superior beats agree in frequency." Because the ratio $\frac{96}{64} = \frac{32 \times 3}{32 \times 2}$ shows 32 cycles of only one beat in each.

In like manner all the other experiments given in detail in the text of June 19 (p. 190) can be accounted for. But there is an explanatory example given by Dr. S. P. Thompson, which, if verified by experiment, must be fatal to my theory of Kœnig's superior beats. This illustration gives 92 inferior beats and 8 superior beats in 492 and 100 vibrations of the primaries; while, according to the theory just sketched, $\frac{492}{100} = \frac{4 \times 123}{4 \times 25}$, shows only 4 superior beats with 392 inferior beats. Only Dr. Kœnig's valuable instruments could satisfactorily decide between them, and I should be glad to know if my building cannot stand. On the other hand, Dr. Molloy's elegant experiment, described in NATURE (vol. xlii. p. 246), is in favour of the cycles of dissimilar beats, inasmuch as these account for his three beats directly from the primaries without the aid of secondaries. In this experiment the primaries were 384 and 255 vibrations in the second; and the ratio $\frac{384}{255} = \frac{3 \times 128}{3 \times 85}$ shows 3 superior beats with 43 dissimilar beats in 129 inferior beats.

Stonyhurst College. WALTER SIDGREAVES.

THE CELL THEORY, PAST AND PRESENT.[1]

I.

IN taking the chair at the first general meeting of the Scottish Microscopical Society, I would offer to the members my hearty thanks for having done me the honour to choose me as the President under whom the work of the Society is to be inaugurated, and during whose incumbency the Society is to begin to substantiate its claim to have an existence amongst the scientific Societies in Scotland.

As myself engaged in biological studies, it is only natural that my attention should have been more particularly directed to the use of the microscope in connection with them, and to the influence which it has exercised on their advancement. Since the time of Hooke, Grew, Malpighi, and Leeuwenhoek, this influence has been continuous and progressive. The improvements in the instrument during the present century have led to discoveries of the utmost value in the structure of plants and animals, and to generalizations of a wide-reaching importance.

One of, if not the most fundamental of these discoveries, was the recognition of the anatomical unit, which we call a *cell*, as a common element in the structure of organisms. Our conceptions of the structure of cells, of the relative function of their constituent parts, and the mode in which cells are developed and multiply, has varied very materially from time to time. I purpose to pass in review those aspects of the subject which have attained prominence, and have influenced the course of investigation.

Dr. Robert Hooke was one of the first men of science to employ the microscope in the study of the structure of plants and animals. A chapter in his "Micrographia" (London, 1665) is entitled "Of the Schematisme or Texture of Cork and of the Cells and Pores of some other such frothy Bodies." This is probably the first use of the word cell in histological description. In the course of this chapter he refers to the lightness of cork, which he compares with froth, or an empty honeycomb. Its substance, he says, is wholly filled with air, which "is perfectly enclosed in little Boxes or Cells distinct from one another." Further, he gives an idea of the dimensions of these cells by stating that about sixty could be placed endways in the $\frac{1}{18}$th part of an inch, and that 1,166,400 could be placed in a square inch. He thinks that they are the channels through which the juices of the plant are conveyed.

The term cell was also employed to express a definite morphological unit by Dr. Nehemiah Grew,[2] who shares with Malpighi the glory of being one of the fathers of vegetable physiology. When describing in his "Anatomy of Plants" the skin of the root (p. 62), he says the parenchymous material is "frequently constructed of exceeding little *Cells* or *Bladders*, which, in some Roots, as of Asparagus, cut traverse, and, viewed through a Microscope, are plainly visible. These Bladders are of different sizes; in Buglos larger, in Asparagus less, and sometimes they coincide and disappear."

In his account of the parenchyma of the bark he again uses the word cells (p. 64), and says that "each is bounded within itself, so that the *Parenchyma* of the *Barque* is much the same thing as to its conformation, which the Froth of *Beer* or *Eggs* is as a fluid, or a piece of fine *Manchet* as a fixed body." These cells are so small as "scarcely, without the microscope, to be discerned;" more usually, however, Grew applies to them the term bladders or vesicles. In the chapter on the vegetation of roots he speaks of the sap swelling and dilating the bladders, and

as being fermented therein, as transmitted from bladder to bladder, and leaving certain of its principles adhering to them. He thus recognized that the cells or bladders played an important part in the nutrition of the plant. Almost, indeed, he seemed to have grasped the idea that they exercised a selective or secreting influence; for, in describing the parenchyma of the fruit of the lemon, he speaks (p. 180) of "those little *Cells* which contain the essential Oyl of the fruit," whilst, he says, in other bladders "lies the acid juyce of the limon."

Malpighi, whose work on the anatomy of plants ("Anatome Plantarum," London, 1675) was almost cotemporaneous with the treatise of Grew, had also seen the structures which Grew named cells or bladders, and had designated them *utriculi*, and believed that they could be separated from each other. In a subsequent treatise ("Opera," vol. ii. p. 41, 1686) he described the lobules of fat in animals as consisting of adipose vesicles.

Leeuwenhoek, in the course of his microscopic inquiries into the structure of plants, gave the name of *globules* to many of the objects which we now term cells, though he expressly states that they were not perfect spheres.[1]

Clopton Havers, in his treatise on the skeleton, described ("Osteologia nova," p. 167, 1691) the vesicular structure of the marrow, and compared it, when seen under the microscope, to a heap of pearls.

Alex. Monro, *primus*, in his work on the bones ("Anatomy of the Humane Bones," Edinburgh, 1st ed., 1726; 2nd ed., 1732), when writing on the medullary structure, stated that it is subdivided "into communicating vesicular Cells, in which the Marrow is contained. Hence it is that the Marrow, when hardned and viewed with a Microscope, appears like a Cluster of small Pearls. This Texture is much the same as what obtains in the other cellular parts of the Body where Fat is collected, only that the Cells containing the Marrow are smaller than those of the *Tunica adiposa* or *cellulosa* elsewhere."

Caspar F. Wolff[2] also recognized that fat was contained in small vesicles, surrounded by a fine membrane. He conceived also that the developing organs, both of plants and animals, consisted of a viscous substance which contained cavities, cells, or bladders which communicated with each other.

Fontana figured the fat vesicles, both free and surrounded by the fibres of the areolar tissue.[3]

Mirbel, in his botanical writings,[4] published at the beginning of the present century, stated that vegetables were composed largely of cells. He described *le tissu cellulaire* as composed of *les cellules*, which were contiguous with each other, so that the walls were in common. These walls were extremely thin and translucent, and sometimes riddled with pores. The term cells was also used both by his contemporaries and immediate successors in their writings on the anatomy of plants.

But anatomists experienced much greater difficulty in distinguishing the presence of cells in the textures of animals. It is true that from the time of Malpighi and Leeuwenhoek, the globules or particles had been recognized in the blood, but it is only within a comparatively recent period that their cellular structure was determined. Both Bichat ("Anatomie générale," Paris, 1812) and Béclard ("Élémens d'Anatomie générale," Paris, 1823), in their important treatises on general anatomy, made no reference to cells as elements of the tissues. Both these authors had chapters *du tissu cellulaire* or *du système cellulaire*, a term which had been in use from the early part of the last century. But by the tela cellulosa or cellular tissue, anatomists meant that form of tissue which we now more appropriately call areolar tissue; the so-called cells of which are not microscopic closed vesicles, but areolæ or spaces bounded by the fibres or laminæ of which the tissue is chiefly composed.[1] Béclard, in his description of the adipose tissue, stated that the lobules of fat consisted of microscopic vesicles $\frac{1}{100}$ to $\frac{1}{800}$ of an inch in diameter. The vesicles, he says, have walls, but they are so thin as to be indistinguishable. The presence of organized vesicles or globules in the tissues of animals had thus been recognized, but it needed further observations and facts in order to bring them into association with the cells of vegetable tissue.

This was supplied by the discovery in 1831 by the great English botanist, Robert Brown, of the "nucleus" or "areola" in the cells of the epidermis, and other tissues in Orchideæ and many other families of plants.[2] Following closely upon this discovery were the observations of Schleiden, published in 1838 ("Beiträge zur Phytogenesis," *Müller's Archiv*, p. 137, 1838), that the nucleus was a universal elementary organ in vegetables. Schleiden also came to the conclusion that the nucleus must hold some close relation to the development of the cell itself, and he consequently called the nucleus a "cytoblast."[3] Schleiden further discovered that the cytoblasts contained one or more minute circumscribed "spots," or "rings," or "points," which he considered to be formed earlier than the cytoblasts, and which were regarded by him as hollow globules, and were subsequently named by Schwann "nucleoli."

The cellular structure of some of the animal tissues had also begun to be recognized. Turpin had noticed the resemblance between the epithelium corpuscles found in vaginal discharges and the cells of plants. Johannes Müller had discovered that the chorda dorsalis of fishes was composed of separate cells provided with distinct walls, though he did not detect a nucleus in them. Purkinje, Von Baer, Rudolph Wagner, Coste, and Wharton Jones had seen the germinal vesicle within the animal ovum. E. H. Schultz had observed the nucleus in the blood globules, and Valentin and Henle had seen it in the cells of the epidermis. The way was thus prepared for a fuller recognition of the essential correspondence between the elementary tissues of plants and animals and for a wider generalization. Science had not long to wait for an observer who could take a comprehensive grasp of the whole subject; and in 1839 Theodore Schwann published[4] his famous researches into the structure of animals and plants, in which he announced the important generalization that the tissues of the animal body are composed of cells, or of materials derived from cells:—

"That there is one universal principle of development for the elementary part of organisms, however different, and that this principle is the formation of cells."

Both Schleiden and Schwann entertained the idea, which had long before been present in the mind of Grew, that a cell was a microscopic bladder or vesicle. In its typical shape they regarded it as globular or ovoid, though capable of undergoing many changes of form. This vesicle possessed a cell-membrane or wall, which enclosed

[1] Samuel Hoole, who translated many of Leeuwenhoek's writings (London, 1799, part 2, p. 178), when describing Fig. 11, on Pl. vi., says that the globules of meal are enclosed as it were in cells, and that some of those cells are represented at H in the figure. Leeuwenhoek, himself, however, in his description of the same figure ("Epistolæ physiologicæ," Delphis, 1719, p. 25), does not use the word cellula.

[3] Fontana (*op. cit.*) figured the "globules" or scales of the epidermis, in which he recognized the nucleus, but he neither gave it a special name, nor knew its importance (Plate i., Figs. 8, 9, 10.)

[4] "Mikroskopische Untersuchungen," 1839; and preliminary notices in Froriep's *Notizen*, 1838.

contents that were either fluid or somewhat more consistent. Either attached to the wall or embedded in it was the nucleus, which in its turn contained the nucleolus. Schwann, however, recognized (p. 176 of Sydenham Society's translation of Schwann's memoir) that many cells did not exhibit any appearance of a cell-membrane, but seemed to be solid, and had their external layer somewhat more compact. As showing, however, the importance which Schwann attached to the cell-wall, I should state that he regarded the chemical changes or metabolic phenomena as he termed them, as being chiefly produced by the cell-membrane, though the nucleus might participate. He explained the distinction between the character of the cell contents and the cytoblastema external to the cell, to the power exercised by the cell-membrane of chemically altering the substances which it is either in contact with or has imbibed, and also of separating them so that certain substances appear on the inner and others on the outer surface of that membrane. In this way, he accounted for the secretion of urea by the cells lining the uriniferous tubes, and for the changes which not unfrequently take place in the cell-membrane itself by thickening or deposition of layers on or within it.

Schwann described the nucleus as either solid or hollow and vesicular, in the latter case being surrounded by a smooth structureless membrane; whilst the contents of the nucleus, other than the nucleoli, were in his view either pellucid or very minutely granulous.

Both Schleiden and Schwann conceived that in the formation of a nucleus a nucleolus was first produced, that around it new molecules were deposited for a certain distance, and then a nucleus was formed. When the nucleus had reached a certain stage of development, new molecules were deposited upon its exterior so as to form a stratum, which when thin was developed into a cell-membrane, but when thick only its outer portion became consolidated into a cell-membrane. Immediately the membrane became consolidated its expansion proceeded by the progressive reception of new molecules; the cell-wall separated from the cell nucleus, and a vesicle was formed; the intermediate space at the same time became filled with fluid, which constituted the cell contents.

Schleiden contented himself with little more than a simple statement of what he conceived to be the process of cell formation in plants; but Schwann entered into an elaborate survey of cell-life both in animals and plants, and founded on it a theory of cells applicable to all organisms.

Schwann conceived that there existed in organized bodies a solid amorphous or fluid substance to which he gave the name *cytoblastema;* this substance might be contained either within cells already existing, or else be situated in the interspaces between cells; and he believed that the cytoblastema for the lymph and blood corpuscles is the fluid lymph-plasma and liquor sanguinis in which these corpuscles float. He held that in the cytoblastema new cells are formed in the manner just described. In animals he says it is rare for cells to arise within pre-existing cells; more usually they arise in a cytoblastema external to the cells already present. Schleiden, on the other hand, maintained that in plants new cells were never formed in the intercellular substance, but only within pre-existing cells. The idea obviously present in the mind of Schwann was that the process of cell formation in a cytoblastema had some affinity with that of crystallization. He figuratively compares the cytoblastema to a mother-liquid in which crystals are formed. He speaks of molecules being deposited around a nucleolus to form a nucleus; of a nucleus growing by a continuous deposition of new molecules between those already existing; and of the cell being formed around the nucleus by a progressive deposition of new molecules; and in more than one passage he indicated that this deposition is a precipitation. He obviously considered the principle of formation of the cell around the nucleus as the same as that of the nucleus around the nucleolus, a process which Valentin subsequently described as heterogeneous circum-position.

But Schwann at the same time showed that, with reference to the plastic phenomena, cells differed from crystals in form, structure, and mode of growth; for whilst a crystal increases only by the external apposition of new particles, a cell grows both by that method and by the intussusception of new matter between the particles already deposited. The difference, he says, is yet more marked in the metabolic phenomena, which he conceived to be quite peculiar to cells. Cells and crystals, however, he considered resembled each other in this point, that solid bodies of a definite and regular shape are formed in a fluid at the expense of a substance held in solution by that fluid, for both attract the substance dissolved in the fluid. Schwann concluded his memoir by advancing, as a possible hypothesis, the view that organisms are nothing but the form under which substances capable of imbibition crystallize; and although this hypothesis involved very much that is uncertain and paradoxical, yet he considered it to be compatible with the most important phenomena of organic life. Schwann inclined, therefore, to a physico-chemical explanation of cell-formation and cell-growth.

Shortly after the publication of Schwann's famous memoir, Henle, who had for some years been engaged in microscopic investigations on the tissues, published his well-known treatise on general anatomy.[1] He attached great importance in cell formation to extremely minute particles, $\frac{1}{8000}$ to $\frac{1}{12000}$ of an inch in diameter, which he called *elementary granules*. He conceived that these appeared in a blastema, that several aggregated together to form a nucleus, in connection with which he thought it not improbable that a cell subsequently formed. He looked upon the elementary granules as the first and most general morphological elements of the animal tissues, and he regarded them as vesicles consisting of excessively minute particles of oil coated with a film of albumen. It should be stated that Henle's observations on cell formation were conducted to a large extent on the products of inflammation, and on the lymph and chyle, in all of which fatty and granular particles abound.

As regards the part which the nucleus plays in the process of cell formation, both Schleiden and Schwann regarded it as of prime importance, though in the subsequent life of the cell they considered that its function terminated. Schleiden stated that, subject to certain exceptions which he enumerated, it is rare for the cytoblast to accompany the cell through its entire vital process—that it is often absorbed either in its original place, or cast off as a useless member, and dissolved in the cavity of the cell. Schwann, whilst contending for the exceedingly frequent, if not absolutely universal, presence of the nucleus, yet held that in the course of time it usually became absorbed and disappeared, so that it had no permanent influence either on the life of the cell or the reproduction of young cells, though he recognized that it remained in the blood corpuscles of some animals. Henle, again, maintained that, as there are nuclei without nucleoli, so also cells exist without nuclei, and that new cells may arise without the least trace of cytoblasts.

At about the same time, and also immediately after the publication of the important investigations by these eminent German observers, a young graduate of medicine of the University of Edinburgh, Dr. Martin Barry, stimulated, he says, by the researches and encouraged by the friendship of Johannes Müller, Ehrenberg, Rudolph Wagner, and Schwann, undertook elaborate researches into the structure of the ovum, more especially in mammals. His results were published in a series of memoirs printed in the Transactions of the Royal Society

[1] "Allgemeine Anatomie," Leipzig, 1841; also French translation by Jourdan in "Encyclopédie Anatomique," vols. vi., vii., Paris, 1843.

of London from 1838 to 1841.[1] In these embryological memoirs, Barry announced several important discoveries. In his first memoir (1838) he pointed out that the germinal vesicle which had been discovered in the mammalian ovum by M. Coste and Mr. Wharton Jones was the first part of the ovum to be formed both in mammals and birds, and he thought that this was probably the case throughout the animal kingdom. In his second memoir (1839) he extended to the mammalian ovum an observation which had been made by Prevost and Dumas on the ovum of the frog, and by Rusconi on the ovum in osseous fish. He described the formation within the rabbit's ovum of the body which he named, and which has been known since his time as the mulberry-like structure. This body arose at first as two vesicles, then as four, and so on in multiple progression, so that Barry was the first to recognize in the ovum of mammals the process which we now know as the segmentation of the yelk. He showed that the vesicles of the mulberry body were cells, and that each contained a pellucid nucleus, and that each nucleus presented a nucleolus. Further, these vesicles arranged themselves as a layer within the zona pellucida.

Barry's third memoir was published in 1840, and as he gave it the subsidiary title of "A Contribution to the Physiology of Cells," it is clear that he regarded his embryological inquiries as having an important bearing on the facts of cell-formation and function. He repeated his observations on the formation of the mulberry-like body, and now recognized that its component cells had been derived from the germinal vesicle, the contents of which entered at first into the formation of two cells, each of which presented a nucleus which resolved itself into other cells, and by a repetition of this process, the cells within the ovum became greatly augmented in number. Further, he stated that the whole embryo at a subsequent period is composed of cells, filled with the foundations of other cells. Although we may not agree with all the details given by Barry in his account of these observations, yet there can be no doubt that he had early recognized the important fact, that in animals new cells arose within pre-existing cells, as Schleiden had affirmed to be the case in plants, and that the nucleus acted as an important centre for the production of young cells. In recognizing the endogenous reproduction of young cells in animals, Barry made an important advance on the view entertained by Schwann, who regarded the endogenous production of cells as quite exceptional amongst animals.

In this same memoir Barry incidentally mentioned that he saw in the ovum of the rabbit a cleft or orifice in the zona pellucida, and that on one occasion he observed what he believed to be the head of a spermatozoon within the orifice. Two years afterwards he read to the Royal Society (Phil. Trans., vol. cxxxiii.; read December 8, 1842) a short paper, in which he announced that he had seen a number of spermatozoa within the ova of the rabbit, and in October 1843 he published a figure of an ovum with spermatozoa in its interior ("On Fissiparous Generation," *Edin. New Phil. Journ.*, October 1843).

In a memoir on the corpuscles of the blood, published in 1841, Barry announced a still more definite conception of the function of the nucleus. He directly traversed the statement of Schleiden, that the nucleus, after having given origin to the cell-membrane, has performed its chief office, and is usually cast off and absorbed; as well as that of Schwann, who had never, except in some instances in fat-cells, observed anything to be produced by the nucleus of the cell. Barry stated that the nucleus is a centre for the origin, "not only of the transitory contents of its own cell, but also of the two or three principal and last formed cells destined to succeed that cell; and in fact, that by far the greater portion of the nucleus, instead of existing anterior to the formation of the cell, arises within the cavity." Further, he says, "young cells originate through division of the nucleus of the parent cell, instead of arising as a sort of product of crystallization in the fluid cytoblastema of the parent cell." He regarded the division of the nucleus in pus corpuscles as not artificially produced by the agency of acetic acid, as was held by Henle and Schwann, but as a part of the process by which cells were produced, and apparently universal in its operation.

In a paper published in 1847, Dr. Barry summarized his observations on the nucleus of animal and vegetable cells, and whilst expressing certain opinions on the mode of formation of the nucleolus and nucleus and the growth of cells which cannot now be accepted, he continued to maintain that cells are descended from an original mother cell by cleavage of the nucleus, and all subsequent nuclei are propagated in the same way by fissiparous generation. Every nucleus, therefore, was a sort of centre, inheriting more or less the properties of the original nucleus of the fecundated ovum, which he conceived to be the germinal spot, and exercising an assimilative power. Dr. Barry's contributions to a correct conception of the development of cells are of the highest importance when viewed in the light of modern observations.

But another Edinburgh inquirer, Mr. John Goodsir, afterwards as Prof. Goodsir the distinguished occupant of the Chair of Anatomy in the University of Edinburgh, was engaged between the years 1842 and 1845 in studying the processes of cell-life, both in healthy tissues and in certain pathological conditions.[1] In his important memoir on secreting structures, published in 1842, he demonstrated from a variety of examples that secretion is a function of the nucleated cell, and he gave, as one of his many illustrations, the cells of the testis containing spermatozoa which were derived from the nuclei of these cells. In the original memoir he was inclined to believe that the cell wall was the structure engaged in forming the secretion; but in a reprint of it in 1845, he modified that view, and gave as his opinion that the secretion would appear to be a product of the nucleus. Goodsir also stated in the memoir of 1842 "that the nucleus is the reproductive organ of the cell, that it is from it, as from a germinal spot, that new cells are formed," and he cited cases in which it became developed into young cells. He subsequently, in a short paper on centres of nutrition, extended this view to the tissues generally. He defined the nutritive centres as minute cellular parts, existing, for a certain period at least, in all the tissues and organs. They drew from the capillary vessels or other sources nutritive material, which they distributed to the tissues and organs to which they belonged. He regarded a nutritive centre as a cell, the nucleus of which is the permanent source of successive broods of young cells, which from time to time fill the cavity of their parent. He called this central or capital cell the mother of all those within its own territory or department. Goodsir also showed that cells were important agents in absorption, ulceration, and inflammation. In inflammation of cartilage, for example, he described and figured the cells in the area affected as increased in size, modified in shape, and crowded with a mass of nucleated cells in their interior, through the agency of which the walls of the corpuscles and the hyaline matrix became absorbed. He also gave illustrations of the multiplication of nuclei within cells in the course of formation of cysts. Corroborative observations on endogenous formation within

[1] Phil. Trans., vols. cxxviii.–cxxxi. The value which was attached to these memoirs at the time may be estimated by the fact that the Royal Society of London awarded to their author in 1839 one of the Royal Medals. The neglect into which Dr. Barry's writings have since fallen is largely due to the disbelief in his subsequent descriptions of the spiral structure of muscular fibre, of blood-corpuscles, and indeed of the elements of the tissues generally.

[1] "On Secreting Structures," Trans. Roy. Soc. Edin., 1842; "On Peyer's Glands," *London and Edinburgh Monthly Journal*, April 1842; "On Structure of Human Kidney," *ibid.*, May 1842; "Anatomical and Pathological Observations," Edinburgh, 1845; also, his collected papers in "Anatomical Memoirs," Edinburgh, 1868, edited by W. Turner.

animal cells were also given by Mr. H. D. S. Goodsir, as confirmatory of the doctrine propounded by his brother on the cell as a centre of nutrition, secretion, and production of young cells. In a research into the structure of the testis in Decapodous Crustacea, Henry Goodsir observed that the head of the spermatozoon corresponded with the nucleus.

The conception entertained both by Martin Barry and John Goodsir of the process of cell-formation and of the function of the nucleus was in the main very different from that propounded by Schleiden and Schwann. Whilst agreeing with Schleiden in holding that new cells were formed within parent cells, they did not look upon the process as one of deposition, in the first instance around a nucleolus and then around a nucleus, but they regarded the nucleus as the prime factor by the division of which new cells were formed. With regard to the free formation of cells, as it was not unfrequently called, by deposition in a cytoblastema situated externally to existing cells, to which Schwann and Henle attached so much importance in animals, they gave no concurrence. Both Barry and John Goodsir had grasped and advocated the fundamental principle, both of the endogenous development of cells from a parent centre and of an organic continuity between a mother cell and its descendants through the nucleus; and the brothers Goodsir had applied this principle in their anatomical, pathological, and zoological researches.

As regards the physiological action of cells, Mr. (now Sir William) Bowman had expressed the opinion[1] that there was a strong presumption that the epithelium of glands assimilated the secretion from the blood; that the secretion might be separated, either by the passage of its elements through the cells, or by the cells undergoing solution or deliquescence, or by the cells being cast off entire with their contents. Mr. (now Sir John) Simon also expressed, in 1845, some important general conclusions on the physiological action of cells ("Essay on the Thymus Gland," London, 1845). He looked upon the cell wall as of secondary importance and of inessential formation, and he regarded the nucleus with the material developed around it as constituting the sole physical evidence of activity in the part. He saw bile and other secretions within cells, and stated that when the products of secretion can be seen within a cell, they are accumulated in the portion which corresponds to the nucleus as though it were the true centre of attraction. Simon also observed the development of spermatozoa within cells, and had seen one end adhering to the relique of a cell, probably its nucleus.

Histologists elsewhere had made isolated observations on the development in the animal body of young cells within parent cells. Even before the publication of Schwann's immortal treatise, Turpin had stated that the corpuscles which he found in vaginal discharges contained a new generation in their interior, and Dumortier had described secondary cells as formed in the ova of snails. These observations exercised, however, no influence on the progress of thought; and Schwann, though referring to them in the preface to his treatise, yet appeared to question their accuracy.

In 1841, Robert Remak published (*Medicinische Zeitung*, p. 127, July 7, 1841) an account of what he saw in the blood corpuscles of the chick, some of which were biscuit-shaped. At each end was a nucleus, and the two nuclei were connected together by a thin stalk which traversed the intermediate part of the corpuscle. He thought it probable from these observations that a multiplication of blood corpuscles through division occurred. He obtained also similar evidence in the blood of the embryo pig, and saw, both in the blood of the horse and of man, red blood-cells formed in the interior of large mother cells. It is customary in Germany to credit Remak with being the first to recognize the division of the nucleus within the cell as a stage antecedent to, and associated with, the division of the cell itself; but from what has already been stated, it will be seen that Martin Barry had preceded him by some months[1] in the recognition of the importance of division of the nucleus in the production of young cells.

In 1843, Albert von Kölliker published (*Müller's Archiv*, 1843) an interesting memoir on the changes which take place in the fertilized ova of various parasitic worms. He described and figured the production in regular progression of young cells within the ovum, and observed that in some cells the nucleus was elongated; in others constricted in the middle, as if about to divide; in others two nuclei were present, each smaller than the single nucleus of adjoining cells, as if they had arisen from the division of a larger nucleus. A legitimate inference from these observations was that, in the formation of young cells, the nucleus of the parent cell divided into two, and that each of these gave origin to a new cell.

The endogenous multiplication of animal cells by division of the nucleus now began to be more widely recognized. It was described by Kölliker and by Mr. (now Sir James) Paget in the blood corpuscles of the embryo, by Kölliker in cartilage and in the giant cells of the marrow of bones, and by various observers in the fertilized ovum. It acquired, therefore, much more importance as a mode of origin of animal cells than was accorded to it by Schwann.

At the time when I began the study of anatomy and physiology in 1850, the current teaching of the schools embraced two methods of cell-formation—the one through the intermediation of existing cells, which might be either by endogenous production within a mother cell through division of the nucleus, or by fissiparous division, or by budding off of a part of a cell; the other by a process of free cell-formation outside existing cells and within a blastema. When I came to Edinburgh in 1854 to act as Demonstrator of Anatomy, I found that the biologists were divided into two hostile forces—the one was presided over by Prof. John Goodsir, whose views on the intracellular origin of new cells I have already explained, and which he systematically expounded in his lectures; the other was led by the then Professor of the Institutes of Medicine, Dr. Hughes Bennett. Dr. Bennett, whose investigations into cell-formation and cell-life had been largely based, like those of Henle, on the study of pathological processes, was led to attach great importance to the granules or molecules which abound in the so-called inflammatory exudations and in purulent fluids. Bennett held that molecules arose in an organic fluid, and that an aggregation of molecules produced nuclei, upon which cell walls may be formed; that the molecule was the primary, elementary, and most simple form of organized matter, and that an aggregation of molecules might even form fibres and membranes without the agency of cells. His views were almost a reproduction of those of Henle, and he advocated them with great vigour and persistency, especially in regard to the production of pus and other products of inflammation.

Pathologists had indeed very generally supported the

[1] Article "Mucous Membrane," in Todd's "Cyclopædia," date probably 1842 or 1843.

[1] Barry's later memoirs were read to the Royal Society of London, May 7, 1840; January 7, 1841; June 17 and 23, 1841. They are illustrated with numerous beautiful figures, in which the division of the nucleus and the endogenous production of young cells are shown. Further, it should be kept in mind that Remak's observation was on a single tissue, the embryonic blood corpuscle; whilst Barry's was a generalization based on a large series of researches on the ovum, blood and mucous corpuscles, epithelium and other cells. John Goodsir, in a footnote to his important paper "On Centres of Nutrition," already referred to, says:—"For the first consistent account of the development of cells from a parent centre, and more especially of the appearance of new centres within the original sphere, we are indebted to the researches of Dr. Martin Barry." Remak subsequently extended his observations, on the multiplication of cells through division of the nuclei, to the ovum, and the cells of the tissues generally. See *Müller's Archiv*, 1852, p. 47, and "Untersuchungen über die Entwicklung der Wirbelthiere," 1855.

theory of the free formation of cells in exudations; but this view, however, was not universally entertained by them. Prof. Goodsir (*op. cit.*, 1845), and Dr. Redfern[1] had shown its inapplicability in inflammation and ulceration of articular cartilages. Prof. Virchow, in a series of papers in his *Archiv*, commencing with vol. i. in 1847, had described the endogenous formation of young cells in pathological structures. In his "Lectures on Cellular Pathology," published in 1858, Virchow, like Goodsir, announced his belief in the mapping out of the body into cell territories. Virchow's conception of the territory was the intercellular substance immediately surrounding a cell, and subject to its influence.[2] He maintained that in pathological structures there was no instance of development *de novo*, but that where a cell existed, there one must have been before. He called it the law of continuous development, which could be formulated in the expression *omnis cellula e cellula*. He adduced a great variety of specific instances to show the diffusion throughout the tissues and organs of nucleated cells, and he established, by a variety of proofs, the important part played by the cell elements, more especially those of the connective tissue, in the inflammatory process and in the production of new formations. He advanced, indeed, such a mass of evidence in support of this position, that the theory of free cell-formation was shortly after abandoned in connection with pathological processes, as it had been some time previously by most observers in normal histogenesis.[3]

(*To be continued.*)

THE CAUSES OF ANTICYCLONES AND CYCLONES.

A MEMOIR presented to the Vienna Academy of Sciences on April 17 last by Prof. J. Hann, giving the results of his study of an anticyclone which lay over Central Europe from November 12 to 24, 1889,[4] brings to a climax one of those investigations that rank as landmarks in the advance of science, and compels us to modify in some important particulars the views now generally current on some of the leading phenomena in meteorology. Next to the facts of the general circulation of the atmosphere, which, in recent years, have been treated of more particularly by Ferrel, Hann, Siemens, Sprung, Oberbeck, and Pernter, the relations between areas of high and low pressure, or anticyclones and cyclones, have played a chief part in the science of atmospheric movements; and indeed in that large and popular department that deals with the weather and its vicissitudes, they may be said almost to monopolize the field. Hitherto, however, excepting in so far as the movements of the clouds afford us any information of the changes in progress in the higher atmosphere, our experiential knowledge of cyclones and anticyclones has been almost restricted to what can be observed within a small distance of the general land-surface. As a rule, a region of high barometer, especially in the winter, is one of low surface temperature, while cyclones, which originate in regions of low pressure, are fed by warm southerly winds. Interpreting these facts by the light of well-known physical laws, it has become the common teaching of our text-books that the former are due to the low mean temperature and therefore increased density of the superincumbent air column, while the latter are brought about by the opposite conditions. The correctness of these views, in so far, at least, as regards anticyclones, was challenged by Dr. Hann as long ago as 1875, in a paper published in the Vienna *Zeitschrift* (vol. x. p. 210), wherein he showed that, as a result both of theory and observation, the cold that prevails in a region of high barometer in winter is really due to terrestrial radiation under the clear skies that are characteristic of such an area, that it is restricted to a stratum of very moderate thickness, and that above this the compression of the sinking atmosphere must induce a high temperature, and consequently greatly reduce its density.

In a subsequent, very suggestive paper, published in 1879 in the fourteenth volume of the same periodical, he discussed more fully the causes of anticyclones, and concluded that they are essentially the same as those which give rise to the two sub-tropical zones of high barometer—viz. the congestion of the upper or anti-trade currents, directed polewards and eastwards, which, owing to the rapid contraction of the circumpolar zones in high latitudes, are partially arrested and forced to return in a lower stratum of the atmosphere. He also expressed the opinion that these areas of congested currents determine the formation of travelling cyclones in the intervals of relatively low pressure, instead of being themselves caused by the overflow of the upper currents from the latter (which is Ferrel's view). Hence that both anticyclones and cyclones have their origin in the circumstances of the general atmospheric circulation, and are, in neither case, primarily due to the heating or cooling of that part of the earth's surface which they temporarily occupy. Some further consequences of high importance were pointed out in this essay. Since the general circulation of the atmosphere is determined by the expansion of the air over the equatorial zone, and the consequent tilting of the planes of equal pressure to form a gradient between the equator and the two poles, the greater frequency of stormy weather in the higher latitudes in winter was shown to follow from the increased activity of the higher or anti-trade currents; the difference of temperature between equatorial and polar and sub-polar regions being at that season at their maximum; and not merely to the contrasted conditions of continents and oceans. Also that any cause tending to increase the heating and expansion of the equatorial atmosphere must intensify both the anticyclonic and cyclonic movements of the temperate and sub-polar zones. In another paper, published in the fifteenth volume of the *Zeitschrift*, he pointed out that this last view received confirmation from the fact, then recently ascertained, that those years in which the barometer ranged below the average in the Indo-Malayan region were years of excessive barometric pressure in winter (but not in summer) in Western Siberia and Russia.

From time to time, as occasion has served, Prof. Hann has continued to verify these views, by investigating the temperature conditions of anticyclones, on the evidence afforded more particularly by the high Alpine and other mountain observatories. He has thus shown that the relatively high temperature prevailing at high levels during periods of intense winter cold at low levels is no exceptional occurrence, but a constant and characteristic feature of anticyclonic conditions. Moreover, that, as a general fact, the temperature at mountain observatories in winter rises and falls directly with the barometric pressure at those elevations, while the reverse holds good at the general ground surface. In summer, the lowest temperatures at mountain observatories coincide also with the lowest pressures at the ground surface; and this he explains partly by the fact that a low barometer is accompanied with stormy and rainy weather, and with snow at the greater elevations, and partly by the dynamic cooling of the ascending air over the region of minimum pressure. The Alpine observatories are, however, less favourably situated for

[2] He first used the term "Zellen Territorien" in his *Archiv*, Bd. iv., 1852, p. 383.

[3] In a lecture which I delivered before the Royal College of Surgeons, Edinburgh, in 1863 (*Edinburgh Medical Journal*, April 1863), I summarized the evidence of the derivation of pathological cell formations from pre-existing cells, and adduced additional examples from my own observations.

[4] "Das Luftdruck Maximum von November 1889 in Mittel Europa, nebst Bemerkungen ueber die Barometer-maxima in Allgemeinen," von J. Hann, W.M.K. Akad.

observing the conditions of cyclones than of anticyclones, since the Eastern Alps lie away from the ordinary tracks of these storms, and are but seldom traversed by their vortices.

In his latest memoir, Dr. Hann describes and compares two striking instances: one of a prolonged period of barometric maximum (from November 12 to 17, 1889), and one of a barometric minimum, on October 1 of the same year. Both of these included the Eastern Alps, and thus afforded an unusually favourable opportunity for contrasting their accompanying temperature conditions up to an elevation of over 3000 metres. The result is that, notwithstanding that the anticyclone occurred six weeks later in the year than the barometric minimum of October 1, the mean temperature of the anticyclonic air-column up to a height of 3 kilometres, was certainly more than 2° C. higher than that of the antecedent minimum. The further conclusions may be given in the words of the memoir.

"That this result holds good, not only for the barometric minimum of October 1, 1889, but as a general fact (the temperatures in both cases being regarded as deviations from the normal of the season), is in itself probable, and has been fully established in my investigation of the temperature of the summit of the Sonnblick during periods of high and low pressure at the earth's surface. One result of this was that the cyclones of the summer half-year bring about a great cooling of the air-column of at least considerably over 3000 metres in height, and cause the greatest depressions of temperature that occur in the summer generally. The mean temperature of the whole air-column in a summer cyclone, from the ground up to a height of certainly over 5000 metres, is lower than in an anticyclone. It is probable that this holds good for winter cyclones also, if their temperature be compared with that in the centre of an anticyclone. The warmth which accompanies winter cyclones at the earth's surface, and which was assumed to characterize the whole air-column, is restricted chiefly to the lower atmospheric layers; the observations on high mountains show that the greatest warmth is always brought by anticyclones; the higher the mountain, the more pronounced is this result.

"At very great elevations, above the cirrus level for instance, the temperature differences of cyclones and anticyclones may again be reversed; possibly, however, not so. For either of these alternative views plausible grounds may be assigned. But this much is certain, that the theory of the causes of cyclonic and anticyclonic movements of the atmosphere must take count of the fact that up to heights of at least 4 or 5 kilometres, the air temperature in the heart of an anticyclone may be (and perhaps always is) higher than that in the centre of a cyclone.

"Thus fall to the ground the views of those who have sought for the cause of these movements in the different specific gravities of the air in cyclones and anticyclones; in the 'upcast' to which the air must be subject in a cyclone. . . .

"So long as the observed temperatures were those only of the earth's surface, one fell almost necessarily into this error, which was so natural and apparently explanatory. Where cold air lay on the earth's surface, there we found high pressures, and *vice versâ;* what could be more self-evident than that the temperature of the air-column was the determining cause of the pressure? It was the observations of mountain observatories, those of peak-summits, that first set us free from this error; and we must now conclude that the temperature conditions of wandering cyclones and anticyclones are the effect and not the cause, that they are the consequence of the movements of the air-masses, of the ascents and descents of the vertical circulation of the atmosphere. There can no longer be any doubt that the pressures in barometric maxima and minima generally are to be explained mainly through these movements of the air. The forces which set up the atmospheric circulation of the higher latitudes, especially in winter, have their origin in the warmth of the tropics—that is to say, in the difference of temperature between the polar regions and the equatorial zone. Cyclones and anticyclones are but partial phases in the general circulation of the atmosphere. The air-currents that set towards the poles as a consequence of the upper gradients are partially resolved in vortices in the higher latitudes, and their progressive movement is chiefly determined by the prevailing westerly direction of the wind currents. The influences of variations of the terrestrial surface, of the heating and cooling of continents and oceans, as well as of the local influx of water-vapour and its condensation, are but of secondary importance. They may however strengthen or destroy the ascending or descending eddies, and modify their paths and their rate of progression.

"These views are such as I have always enunciated (for a long time, indeed, without any apparent result) in opposition to the then prevalent theories of the local origin of barometric minima through the agency of condensing water-vapour (as contended by Mohn, Reye, Loomis, and Blanford). They now begin to make way and to prevail. Most clearly is this seen in the case of Loomis, who, in the course of his own persistent study of the behaviour of barometric minima and maxima, has been compelled by degrees to give up the 'condensation theory' to which he formerly adhered so strongly, and to ascribe the origin as well as the progressive movement of cyclones to the general circulation of the atmosphere."

After a cursory recapitulation of some of the leading demonstrations of his previous writings, to which brief reference has been made above, Prof. Hann concludes:—

"This theory is not merely deductive, nor is it put forward simply as a speculation. On numerous occasions I have demonstrated step by step how it agrees with observation in all its details, so that I may fairly claim the right of priority for its establishment."

This claim will doubtless be readily admitted, and it adds one more to the many great services which its author has already rendered to the cause of physical meteorology, and which have long since won for him his universally acknowledged place in the forefront of modern meteorological science. As regards the genesis of anticyclones, for the study of which the Sonnblick, Hoch Obir, and Santis Observatories have afforded him numerous opportunities, which he has turned to the best account, Prof. Hann's conclusions appear to be unassailable. And in respect of the cyclones or barometric minima of the temperate and sub-Arctic zones, although the evidence is perhaps less decisive, and its conclusiveness may possibly yet be challenged in some particulars, it must at least be conceded that his arguments are entitled to much weight; and the facts adduced greatly weaken, if indeed they do not altogether destroy, the validity of the views hitherto prevalent. For my own part, I am quite prepared to admit the probability that these barometric minima are, as he contends, in their origin, great eddies in the higher atmosphere, and are not determined by the high mean temperature of the air-column over the spot in which they first appear.

But I cannot admit that these conclusions can be extended to the case of tropical cyclones. Prof. Hann does not indeed expressly claim such extension; but, on the other hand, he does not expressly limit their application to the storms of extra-tropical latitudes, and from the fact that, in a paper recently published in the *Meteorologische Zeitschrift*,[1] he discusses the conditions of both these classes of cyclones without insisting on any fundamental distinction between them, it must, I think, be in-

[1] "Bemerkungen über die Temperatur in den Cyclonen und Anticyclonen," *Met. Zeitschr.*, Heft 9, September 1890.

ferred that he contemplates as at least a high probability that they originate from like causes. Moreover, in the paragraph quoted above, he refers to myself as an upholder of the condensation theory, in terms that seem to imply that he regards me as an opponent, the fact being that I have never contended that this theory is applicable to the case of other than tropical cyclones, or, to be exact, of other than those of Indian seas. To this contention I must still adhere; but as the discussion of the question would unduly extend the limits of this notice, I reserve it for another occasion. HENRY F. BLANFORD.

ON THE ANATOMY AND DEVELOPMENT OF APTERYX.

IN a paper read before the Royal Society on April 17 of this year, Prof. T. Jeffery Parker, F.R.S., of Otago University, gives an account of his researches on the anatomy and development of the Kiwi (*Apteryx*) which are of especial interest, as so few detailed observations have been recorded on the development of any of the flightless birds (*Ratitæ*). Moreover, the comparisons which are given of the different species of *Apteryx;* the account of the sexual differences, and the variations seen within the same species; and the tables showing the relative proportions of the various regions of the body in different stages of development, illustrating the "law of growth," add greatly to our knowledge of this remarkable genus. A number of new terms are proposed in the description of the skeleton, and a new method of writing the vertebral formula of birds is adopted. Notes are given with regard to the presence of uncinate processes and to the structure of the foot in *Dinornis*.

The chief materials on which the investigation is based consist of a number of embryos of the three common species of *Apteryx*, which naturally group themselves into ten stages (A–K); an eleventh stage (L) is furnished by a bird a few weeks old, a twelfth (M) by the skeleton of an adolescent specimen, and a thirteenth (N) and fourteenth (O) by odd bones of young birds; the adult may be considered as constituting a fifteenth stage. The embryos were, for the most part, well preserved, but not sufficiently well for the purposes of exact histological study. The single embryo belonging to stage A corresponds in most respects to a chick of the fourth day.

The paper is illustrated with over 300 figures, and gives so many technical details as to the structure and development of the skeleton, and as to the muscles of the wing, the brain, and the eye, that it is impossible here to give anything approaching a satisfactory abstract of the whole, which will appear shortly in the Philosophical Transactions. The chief results of more general interest, as bearing on the phylogeny of *Apteryx* and of the Ratitæ generally, may be briefly summarized as follows.

In stage A, the limbs have already attained their permanent position, so that, if the backward shifting of the appendages so noticeable in the chick occurs in *Apteryx*, it must take place at an unusually early period. In stage C, corresponding with a sixth-day chick, there is a well-marked operculum growing backwards from the hyoidean fold, and covering the third (? and fourth) visceral cleft. A rudiment of this structure is seen in the preceding stage.

From the first appearance of the feather papillæ there are well-marked pterylæ and apteria, most of which can be made out with tolerable distinctness in the adult.

The wing of the adult has a well-marked pre- and post-patagium, and amongst its feathers may be distinguished nine or ten cubitals, two or three metacarpals, one mid-digital, and a row of tectrices majores. The barbicels of the feathers are slightly curved. The fore-limb passes through a stage in which it is a tridactyle paw with subequal digits, followed by one (stage F) in which it is a typical wing with hypertrophied second and partially atrophied first and third digits. The variability of the muscles of the wing is noteworthy, and the evidences of degeneration are very clear; a number of wing-muscles, not mentioned by Owen, are described.

The nostril has acquired its final position at the end of the beak in stage E; up to the middle of incubation the whole respiratory region of the olfactory chamber, from the anterior nares to the commencement of the turbinals, is filled with a solid mass of epithelial cells, through which a passage is formed at a later period. The turbinals are unusually well developed. A pecten is present in the eye during late embryonic life. At no stage is there any trace of the caruncle or "egg-breaker" at the end of the beak.

As regards the skull, it may be mentioned that the head of the quadrate is provided with two articular facets; no intertrabecula could be observed; there is no interorbital septum; Jacobson's cartilages are present; and the hyoidean portion of the tongue-bone ossifies late, and is obviously degraded.

The vertebral column and hind-limb are typically avian, both as regards structure and development, and these typical characters appear early in the pelvis. There is a pygostyle. The sternum and shoulder-girdle, as well as the wing, are very variable, indicating degeneration; their position in stage E resembles that seen in Carinate birds. Vestigial acromial, procoracoid, and acrocoracoid processes are present, the procoracoid being well marked in comparatively late embryonic life. There is no trace of clavicles. A vestigial keel is occasionally present in the sternum; but before considering the peculiarities in the development of the sternum as of fundamental importance, it will be necessary to study that of the flightless Carinatæ, and especially of *Stringops*.

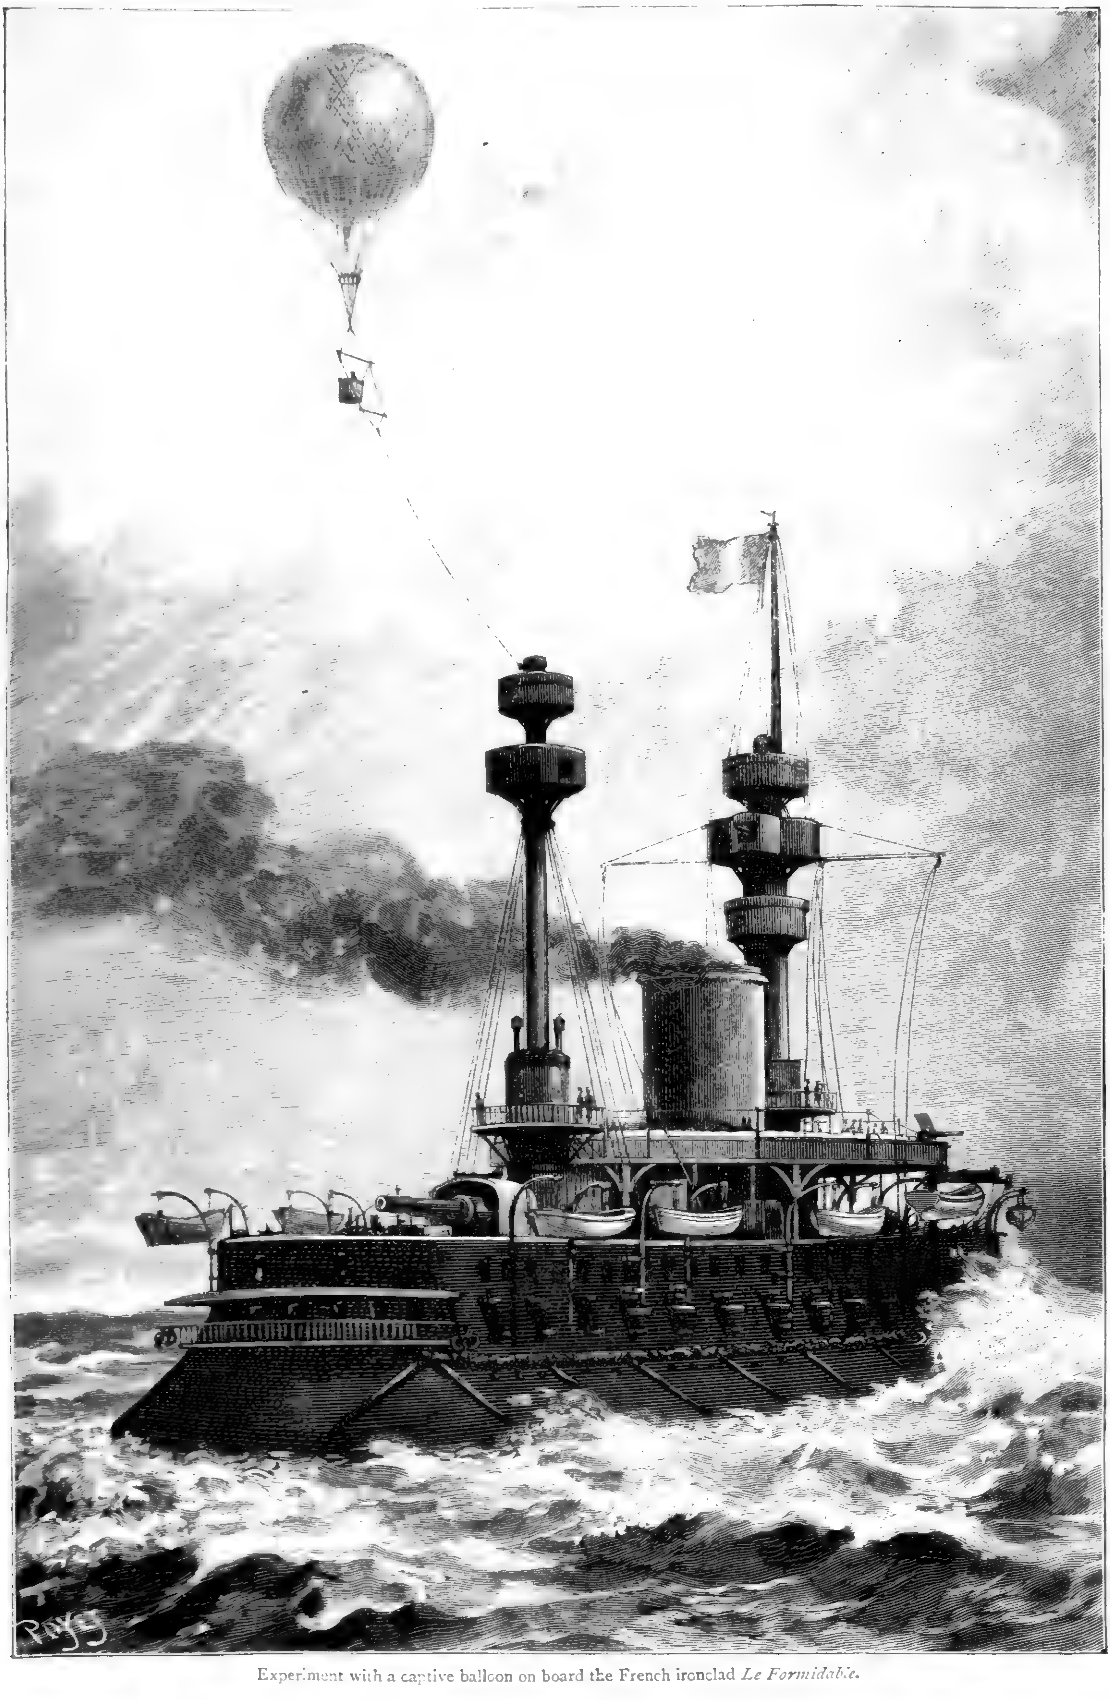
The brain passes through a typical avian stage with lateral optic lobes. The mesencephal is unusually small from the first; in stages D—F the optic lobes are dorsal; in G they become lateral by the transverse extension of the optic commissure or median portion of the roof of the mesocœle; in H they are already ventral, although larger proportionally than in the adult. The diencephal becomes tilted backwards in later stages, its dorsal wall becoming posterior, and the foramen of Monro postero-dorsal instead of antero-dorsal. The anterior commissure and corpus callosum are large. The cerebral hemispheres are of unusual proportional length, and partly cover the cerebellum.

The greater number of the characters enumerated support the view that *Apteryx* is derived from a typical avian form capable of flight;[1] but on the other hand, the total absence of rectrices tells against this theory. Many characters, again, indicate derivation from a more generalized type than existing birds; while in other points *Apteryx* exhibits greater specialization than other birds. The general balance of evidence seems to point to the derivation of both Ratitæ and Carinatæ from an early group of typical flying birds or *Proto-Carinatæ*.

CAPTIVE BALLOONS.

SOME important experiments with captive balloons have lately been made in the Mediterranean squadron of the French navy. By the courtesy of the editor of *La Nature*, we are enabled to give, on the next page, a representation of the most interesting of these experiments, which was made on board the ironclad *Le Formidable*. All the officers who mounted in the car declare that it afforded an excellent point of observation. In clear weather they could distinguish, from Lagoubran, all the details of the coast from the entrance to Mar-

[1] The attitude assumed during sleep also supports this view.



Experiment with a captive balloon on board the French ironclad *Le Formidable*.

seilles to the eastern extremity of the Islands of Hyères. No ship within a radius of from 30 to 40 kilometres could have escaped observation. With a cable of silk, the balloon could rise in calm weather to a height of 400 metres.

It is evident from the success of these experiments that captive balloons may be a most important aid to those who hereafter make use of them in naval warfare. The subject has attracted the attention of the naval authorities in Germany, and at Wilhelmshaven a captive balloon was sent up recently from the *Mars*. We are glad to learn that the English Admiralty has taken up the question.

THE COCO-DE-MER IN CULTIVATION.

WITH only one exception, the palms of the Seychelles have long since proved amenable to cultivation in our tropical plant-houses. The genera *Stevensonia*, *Verschaffeltia*, *Roscheria*, *Latania*, *Dictyosperma*, *Acanthophœnix*, *Hyophorbe*, and *Chrysalidocarpus*, which are peculiar to this small group of islands, and which rank amongst the noblest of a noble family, are all well known in European collections of palms, their cultivation presenting no more difficulty than that of tropical plants generally. The coco-de-mer or double cocoa-nut (*Lodoicea seychellarum*) has, however, so far proved unmanageable under artificial treatment, notwithstanding that many attempts have been made to establish it at Kew and elsewhere. So long ago as the year 1827, Sir William Hooker published a series of figures and a description of the coco-de-mer in the *Botanical Magazine*, and recorded the arrival of living nuts of it at Kew, where, he says, "we cannot doubt of soon seeing them flourishing in our stoves." But they failed to grow, and although dozens of nuts have since been tried at Kew, not one ever got beyond the first stage of germination.

The absence from our collections of living examples of this most remarkable palm is most disappointing to all students of the order. At Kew we have lately been successful in establishing living plants of the Ita (*Mauritia flexuosa*) and Bussu (*Manicaria saccifera*) palms of the Demerara swamps, and the Doum (*Hyphæne thebaica*) and Palmyra (*Borassus flabelliformis*) palms of Africa. These successes stimulated the desire once more to obtain a living plant of the coco-de-mer.

Application was therefore made in January last year, through the Secretary of State for the Colonies, for a supply of fresh nuts from the Seychelles, and at the same time directions for packing and forwarding the nuts were sent to Mr. C. Button, the Conservator of Forests at those islands. The Administrator, Mr. T. Risely Griffith, took a warm interest in the matter, and through his kind exertions several consignments of nuts were received, of which four germinated. Two of these are probably too weak to live, but the other two are in a most promising condition. The strongest has a radicle 3 feet 8 inches long, and 12 inches in circumference at the end where the plumule is developed. This is now a foot long, and is pushing a perfect leaf.

In a note by the late General Gordon on the germination of the double cocoa-nut, it is stated that the nut is planted horizontally, without the husk, when it sends out a sprout some 12 feet long, which pushes up the young plant at a distance of 12 feet from the nut. The longest "sprout" we have had at Kew has not exceeded 4 feet. Nor can it be made to grow horizontally, the point turning down perpendicularly however often its position may be altered. At Kew the nuts were planted in a bed of cocoa-nut fibre, and kept at a temperature of 80°–85° F. They were planted in June 1889.

Mr. Button had kindly undertaken to plant a nut in a Wardian case, and treat it according to our instructions until it had germinated and developed the plumule before despatching it to Kew. A nut thus treated arrived in July last in the most promising condition. The radicle is 1 foot 10 inches long, and the plumule is 7 inches in circumference at the base. It has a stout sheath-leaf, and a normal leaf 3 feet 2 inches long, 3 feet wide, with thirty-six folds. The midrib is curved, and the blade at present folded double. The texture is exceptionally firm, and the colour a deep green.

Full-sized trees of the coco-de-mer attain as much as 150 feet in height, with a smooth trunk about a foot in diameter. The leaves form an immense crown on the top, and each leaf is 20 feet long and 10 or 12 feet wide. The male and female flowers are on separate plants: the male inflorescence is shaped like a huge willow catkin, its length being 5 to 6 feet by 4 inches in diameter; the female is from 2 to 4 feet long, and it bears from six to ten fruits, each of which weighs from 25 to 30 pounds. They take seven years to mature, and sometimes hang two years on the tree after they are ripe. The process of germination extends over about two years. According to General Gordon, the trees begin to fruit when about forty years old, and attain maturity in 120 years.

Royal Gardens, Kew. WILLIAM WATSON.

[The coco-de-mer is at present confined to Praslin and Curieuse, two of the islands of the northern group of the Seychelles Archipelago. It undoubtedly runs some risk of extinction from the long period which the nuts take to germinate, and from the fact that, the trees being of different sexes, isolated females may easily escape fertilization. Its cultivation in the Botanic Gardens of the tropics is therefore of considerable importance.

Plants have long flourished in the Royal Botanic Gardens at Peradeniya, and the following extract from a letter from the Director, Dr. Trimen, F.R.S., to Kew, records the interesting circumstance of a male plant having flowered:—

"*Peradeniya*, August 12, 1890.

"You will be interested to hear that one of our Lodoicea palms put out a ♂ inflorescence last month. The tree is thirty-nine years old. To my great disgust, when the spike was about 6 inches long, some visitor cut it off with a blunt knife, and I found it on the ground. The flowers were all formed, and the structure exactly as described by Sir W. Hooker in the *Botanical Magazine*. I hope my other tree will prove ♀, but that is much younger."

Sir John Kirk also succeeded in establishing the palm in his garden at Zanzibar.

The Government of the Seychelles has long watched with care the preservation of the existing groves of the palm, and pains are now taken to fertilize the female plants artificially, and to plant the seeds.—W. T. T. D.]

NOTES.

WE have to announce the death of Pierre de Tchihatchef, which took place at Florence on the 13th ultimo. This gentleman was perhaps best known as a botanist, though his principal literary work, "Asie Mineure: Description Physique, Statistique, et Archéologique de cette Contrée," took a much wider range. Prior to 1857, he travelled ten years in Asia Minor and Armenia, and, besides the work named, he published a large number of separate papers on a variety of subjects, chiefly however on botany and geology, commencing in 1840. Like so many Russians, he appears to have been an accomplished linguist, and wrote German and French with equal facility. He resided some years in France, and was one of the original members of the Botanical Society of France, founded in 1854. His "Botany of Asia Minor" forms the third part of the work named above, and consists of two volumes of letterpress, and a volume of plates by Riocreux. Pierre de Tchihatchef was also the author of an admirable French translation of Grisebach's "Vegetation der Erde." But this was something more than a translation, for it was cast in a better mould than the original, and contained much new matter, including an essay on the geological formation of oceanic islands.

WE regret to have to record the death of Dr. Alexander John Ellis, F.R.S. We reprint from the *Times* the following notice of his career:—Dr. Ellis, whose original name was Sharpe, died at his residence in Auriol Road, West Kensington, on October 28. He was born in Hoxton in 1814, and educated at Shrewsbury, Eton, and Trinity College, Cambridge, of which he was elected a scholar in 1835, and graduated B.A., being sixth wrangler and first in the second class in classics, in 1837. He was elected a Fellow of the Cambridge Philosophical Society in 1837, of the Royal Society in 1864 (being a member of the Council for 1880–82), of the Society of Antiquaries in 1870, of the College of Preceptors in 1873, and a life governor of University College, London, in 1886. He was President of the Philological Society during 1872–74, and also 1880–82. He was also a member of the Mathematical Society of London, of the Royal Institution, of the Society of Arts, and honorary member of the Tonic Sol-Fa College. Dr. Ellis was a voluminous author, his works including "The Alphabet of Nature," 1845; "Essentials of Phonetics," 1848; "Plea for Phonetic Spelling," 1848; "Universal Writing and Printing," 1856; "Early English Pronunciation, with special reference to Chaucer and Shakespeare," 1869–86; "Glossic," 1870; "Practical Hints on the Quantitative Pronunciation of Latin," 1874; "On the English, Dionysian, and Hellenic Pronunciation of Greek," 1877; "Pronunciation for Singers," 1877; "Speech in Song," 1878; together with numerous other works and tracts on music and phonetics. He received the silver medal of the Society of Arts for three papers in connection with the "Musical Pitch" at home and abroad.

DR. F. R. JAPP, F. R.S., Assistant Professor of Chemistry in the Normal School of Science, South Kensington, has been elected Professor of Chemistry at the University of Aberdeen.

AT the Royal Institution of Great Britain, on Monday, Mr. Victor Horsley, F.R.S., was elected Fullerian Professor of Physiology for three years.

THE Secretary of State for India has appointed Mr. Arthur W. Thomson, C.E., B.Sc., of the Glasgow and West of Scotland Technical College, to be Professor of Mechanism and Applied Science in the College of Science, Poona.

WE are glad to learn that the accommodation at the disposal of the Botanical Department in the University College, London, has been greatly augmented. Hitherto, all the botanical work, other than lectures, has been confined to the single general laboratory in the north cloister. In the adjacent Birkbeck building, from which the school of technological chemistry has been transferred to another portion of the College, several rooms have now been set apart for the various branches of botanical teaching; and the room in the north cloister has been fitted as a museum and general botanical laboratory. During the building operations, just concluded, the workmen found three large chests in which Prof. Lindley (who died in 1865) had stowed away a series of fossil types, representing the chief genera of plants occurring in the Coal-measures. This collection is, of course, a valuable accession to the botanical museum.

ON Monday the Corporation of Brighton obtained formal possession of the museum in Dyke Road, containing the collect tion of British birds formed by the late Mr. E. T. Booth, and bequeathed by him to the town. A large assembly, including some specially invited men of science from London, gathered on the occasion. The key of the building having been handed to the Mayor of Brighton, Alderman Manwaring, he said that he trusted the collection was the beginning of such a natural history museum as no other town in the kingdom could boast of possessing. The gathering was addressed by Prof. Flower, of the British Museum, who said the collection was in many respects unrivalled in the kingdom. The homes in which the birds dwell were carefully and accurately reproduced in a manner that had never before been achieved. In that museum some of the specimens of taxidermy were very fine. All were above the average, and he did not believe there was a single bad one among them. It would have been a national calamity for such a collection to be dispersed or destroyed, and when it was offered to the British Museum he should have advised the Trustees to take it over had it not been intimated to him that the Corporation of Brighton were willing to take it and maintain it for the future benefit of mankind. Though it would have been a great privilege to him to be its official guardian, he rejoiced to find it was going to remain in Brighton, where it was formed, and in the neighbourhood of which many of the specimens were obtained.

THE following have been elected as officers of the Cambridge Philosophical Society for the ensuing year: President:—Prof. G. H. Darwin, F.R.S. Vice-Presidents: J. W. Clark, Trinity; Prof. Babington, F.R.S., St. John's; Prof. Liveing, F.R.S., St. John's. Treasurer: R. T. Glazebrook, F.R.S., Trinity. Secretaries: J. Larmor, St. John's; S. F. Harmer, King's; E. W. Hobson, Christ's. New Members of Council: Dr. Alex. Hill, Downing; Dr. A. S. Lea, Caius; A. Harker, St. John's; L. R. Wilberforce, Trinity.

THE Meteorological Council have published the meteorological observations made at stations of the second order (*i.e.* observations taken at 9h. a.m. and 9h. p.m. each day) for the year 1886. The present volume differs in several important particulars from those of previous years: the distribution of stations is much more complete, for, although the number for which observations in detail are published has been reduced, on the other hand the summarized observations have been considerably increased, and include the records from the observatories in connection with the Office. Some alterations will also be found in the tables, both as regards the information given and the form in which it appears: the barometer observations are no longer reduced to sea-level, owing to the uncertainty which attaches to the formula for reduction when the height of the station is considerable. In the hygrometrical values, the differences between dry- and wet-bulb readings are given under the heading of "Depression of Wet Bulb." In other respects, the general plan of the publication is the same as in previous years, and includes observations made at some selected stations of the Royal and Scottish Meteorological Societies.

IN the *Bollettino Mensuale* of the Italian Meteorological Society for September, Prof. P. Busin publishes the results of his discussion of the diurnal probability of rain, calculated from long series of observations for three of the principal Italian cities, obtained by dividing the number of days of rain in a given period by the number of years of observation for the same period. He concludes that the tables show that barometric depressions do not bring rainy weather, or anticyclones fine weather, so frequently as generally supposed, and that such tables are more to be relied on by agriculturists than telegraphic forecasts of rain, owing to the variability of this element in adjacent localities. Although we cannot entirely agree with this view, there can be little doubt that such investigations may be valuable aids to the study of weather changes, if used in connection with telegraphic information of existing conditions.

WE have received two pamphlets on the "Aurora" and "Forces concerned in the Development of Storms," by Mr. M. A. Veeder. In the former he finds that the phenomena depend on the rotation of the sun, and he mentions the remarkable coincidence in time of their sudden appearance and gradual fading with the solar disturbances that appear on the sun's eastern limb. He also suggests that thunderstorms "may be a reciprocal or alternative method of manifestation of forces, which, under other conditions, find their expression in the aurora." In the latter pamphlet, the working hypothesis adopted is that the distribution of atmospheric pressure as a whole may be determined to an important extent by the fact that the earth is a magnet, and that its magnetic properties are variable. In fact, convection-currents are of secondary importance, for he says that "the bringing of warm air from the tropics, or the bringing of cold air from the polar regions, is the effect, and not the cause, of the redistribution of pressure." Thus, if these magnetic forces, associated with magnetic induction from the sun, influence the atmosphere and mass it together in any particular way, equilibrium is maintained as long as these forces do not vary, but, as soon as they do, readjustment sets in, and eddies, storms, &c., are the result.

THE latest Report on the economical condition of Switzerland, from the British Legation at Berne, refers to the subject of technical education in that country. Subventions to the amount of £12,854 were granted by the Federal Government during the past year to the various technical schools existing in the different cantons. Among the more important of these schools is the Technikum at Winterthur, the various silk and cotton weaving schools in the cantons of Zürich, Basle, &c., and the schools of horology in the cantons of Geneva, Berne, and Neuchâtel. The Federal Government have, moreover, on more than one occasion been invited to consider the question of subsidizing schools of commerce, and applications for financial assistance have been addressed to them by the cantons of Geneva and Zürich, in which schools of this nature are already established. The Federal Council, while admitting that it is their duty to encourage in every way the establishment of schools in which youths may be trained for the various branches of commercial life by an education especially adapted to that end, have nevertheless decided that they would not be justified in thus adding to the expenses of the confederation until the equilibrium has been restored in the Federal budget.

WITH reference to our note, last week, about scientific guide-books, a correspondent writes:—"For Switzerland I should like to recommend the 'Botanist's Vade-Mecum,' published by the 'Librairie Saudoz' of Neuchâtel. It was compiled by Mr. Paul Morthier, Professor of Botany at the Neuchâtel Academy, and President of the International Society of Botanists. It has already passed through two or more editions, and the price is about 2*s.* 6*d.*"

MESSRS. CASSELL have issued, for the National Association for the Promotion of Technical and Secondary Education, a "Guide to Evening Classes in London." This compilation ought to be of great service to what is now, happily, a large class of students. Full information is given as to all the chief classes, elementary and advanced, that are to be held during the coming winter in the capital.

A SUPPLEMENT to the third volume of the *Internationales Archiv für Ethnographie* has been issued. It consists of some interesting ethnographical notes, by Dr. Max Weber, on Flores and Celebes. The paper is admirably illustrated.

A WEEKLY review, entitled *L'Université de Montpellier*, is about to be issued at Montpellier. It will contain information concerning the University; an abstract of the most interesting lectures in science, literature, and art; and original papers by men of science in the town and neighbourhood.

THE following is a list of the edible fungi exhibited for sale in the market of Modena during 1889:—*Amanita cæsarea, A. ovoidea, A. strobiliformis, Lepiota excoriata, L. naucina, Armillaria mellea, Pleurotus ulmarius, P. glandulosus, Entoloma Rhodopolius, Pholiota mutabilis, P. Aegerita, Psalliota campestris, Morchella esculenta, M. conica, M. rimosipes, Helvella monachella, H. crispa, Peziza vesiculosa, P. cerea, P. Acetabulum, Tuber magnatum, T. æstivum, Balsamia vulgaris.* By far the greater number of these species are also natives of Britain.

M. KUZNETSOFF, who has spent several years in the study of the flora of the Caucasus, sets forth in the last issue of the *Izvestia* of the Russian Geographical Society the following interesting conclusions:—The flora of the Kutais and Tchernomorsk regions, on the eastern coast of the Black Sea, belongs, as already known, to the Mediterranean region of evergreen trees. Next comes the region of West European flora, characterized by the extension of the beech-tree, and offering on the slopes of the mountains the very same subdivisions as we are accustomed to see in the Alps. That region extends over the provinces of Kuban and Terek as far east as the water-parting between the Terek and Sulak rivers. The territory to the east of it was formerly thought to have a flora more akin to that of Asia, but a distinctly European flora appears again on the eastern slopes of the Daghestan plateau turned towards the Caspian Sea; while the dry Daghestan plateau itself has a flora decidedly recalling that of the highlands of Central Asia. M. Kuznetsoff explains these differences by the moister climate of the Caucasus highlands, due to the proximity both of the Black and of the Caspian Sea. But it may also have a deeper cause. In fact, the plateaus of Daghestan cannot but appear to the orographer as a continuation of the geologically oldest plateaus of Asia Minor, now separated from the main plateau by the relatively much younger chain of the Caucasus. Referring to the vegetation of the Caucasus during the Tertiary epoch, when the Caucasus was a vast island surrounded by Tertiary seas, M. Kuznetsoff considers that the flora of Daghestan has undergone the greatest change since the Tertiary epoch. The floras of both the Western and the Eastern Caucasus have maintained more of their old characters, owing to less change having gone on in their climate, which has remained moist; and the vegetation of the Black Sea coast, which has a climate very much like that of the Japan archipelago, has retained still more of the aspects it had during the Tertiary epoch. Further exploration will be necessary to show how far climate alone can account for the present characters of the flora of Caucasus.

FURTHER details are given by Prof. Curtius in the current number of the *Berichte* concerning his new gas, hydrazoic acid, N_3H. Since the first announcement, a better and much readier mode of preparing the gas has been discovered. Instead of reacting with hydrazine hydrate upon benzoylglycollic acid, it is found much more convenient to commence by preparing the hydrazine derivative of hippuric acid,

$$\begin{array}{l} C_6H_5 \\ | \\ CO \\ | \\ NH \\ | \\ CH_2-CO-NH-NH_2 \end{array},$$

a substance much more readily obtained. This compound is converted into its nitroso-derivative,

$$C_6H_5-CO-NH-CH_2-CO-N\begin{matrix}\diagup NO \\ \diagdown NH_2\end{matrix},$$

by treatment with sodium nitrite and acetic acid at a temperature about 0° C. Nitroso-hippurylhydrazine is much more permanent than the corresponding nitroso-compound of benzoylhydrazine, used in the earlier experiments, and the yield is 90 per cent. of the theoretical. The well-washed crystals of this nitroso-compound are next dissolved in dilute caustic soda, and the solution warmed for a short time upon the water-bath. The alkaline solution is afterwards placed in a flask connected with a condenser and fitted with a dropping funnel. Dilute sulphuric acid is now allowed to slowly drop into the liquid, which is maintained at the boiling temperature. Under these circumstances an aqueous solution of hydrazoic acid distils over. The distillate is allowed to flow into a solution of silver nitrate, when the silver salt, silver azoate, N_3Ag, is precipitated. The silver salt is afterwards dried at 60°–70°, at which temperature no danger attends the operation, and decomposed by sulphuric acid diluted with eight times its volume of water, when hydrazoic acid gas is liberated, contaminated with only a trace of moisture. It appears that the aqueous solution of the free acid is almost as explosive as the silver and mercury salts. Upon one occasion, when attempting to fuse the drawn out end of a tube containing about 2 c.c. of a 27 per cent. solution, Dr. Curtius had a very narrow escape of serious injury, the whole exploding with a fearful detonation, and shattering the glass tube into dust. Several of the azoates explode when a beam of coloured light is thrown upon them; thus barium azoate, BaN_6, explodes when exposed to a strong green light, as does also the still more explosive silver azoate. A concentrated solution of hydrazoic acid appears to be able to dissolve gold, with formation of a red solution of gold azoate.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. Charles E. Flower; an Azara's Fox (*Canis azaræ* ♂) from South America, presented by Mr. H. M. Dodington; an Alligator (*Alligator mississippiensis*) from the Mississippi, presented by Mr. A. Schafer; two Black-faced Spider Monkeys (*Ateles ater* ♀ ♀) from Peru, deposited.

OUR ASTRONOMICAL COLUMN.

THE ROTATION OF VENUS.—M. Perrotin, the Director of Nice Observatory, presented a note on the rotation of the planet Venus, at the meeting of the Paris Academy held on October 27. The observations described in the note were undertaken for the purpose of testing the conclusions recently arrived at by Signor Schiaparelli. They extend from May 15 to October 4. In the interval the planet has been observed on 74 days, and 61 maps made of its appearance. The whole of the observed facts leads M. Perrotin to the following conclusions:—

(1) The rotation of the planet is very slow, and is made in such a way that the relative position of the spots and terminator do not experience any notable change during many days.

(2) The time of rotation of the planet does not differ from its sidereal period of revolution (about 225 days) more than thirty days. My observations will easily accommodate themselves, however, to a rotation of which the period is from 195 to 225 days.

(3) The axis of rotation of the planet is almost perpendicular to the plane of its orbit. The displacement of the white region observed at the northern edge indicates that the difference does not exceed 15°, as was admitted by Schiaparelli.

These conclusions, therefore, support those deduced by Schiaparelli from an extended discussion of all the observations of the planet.

SPECTRUM OF THE ZODIACAL LIGHT.—Prof. C. Michie Smith has published a series of observations made at Madras of the spectrum of the zodiacal light (Proc. Roy. Soc. Edinburgh, April 7, 1890). He used a spectroscope specially designed for observing and photographing this spectrum, and records:—"In all my observations, which have been carried on at intervals since 1875, the spectrum has appeared continuous and free from bright lines except during the spring of 1883, and even then the lines were not seen with sufficient distinctness to make their existence certain. The estimated position of the supposed line, wave-length 558, differs but little from that of the auroral line (wave-length 556·7) which was observed by Angström in the zodiacal light spectrum in 1867. He was, however, observing at Upsala, where the auroral spectrum can often be seen in almost all parts of the sky, even when the aurora itself cannot be detected. . . . There would seem to be very little risk of obtaining the auroral spectrum in Madras, and I think that if the bright line seen was real, and not imaginary, it must have been due to the zodiacal light."

These observations indicate a periodic appearance of the 558 line in the zodiacal light spectrum. They also support the idea that the origin of the line is the first fluting of manganese at λ 5576.

D'ARREST'S COMET.—This faint comet (*d* 1890), re-discovered by Mr. Barnard on the 6th ult., may be observed near the following positions:—

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON Wednesday and Thursday evenings of last week, the 29th and 30 ult., a general meeting of the Institution of Mechanical Engineers was held. The chief business was the reading and discussion of the following two papers: on tube-frame goods waggons of light weight and large capacity, and their effect upon the working expenses of railways, by Mr. M. R. Jefferds, of London; and on milling cutters, by Mr. George Addy, of Sheffield.

Mr. Jefferds is an American engineer who has come over to this country with a view to introduce the tube-frame waggon into England. It should be explained that the tube-frame differs from the ordinary frame of an English railway truck chiefly in the fact that, in place of the timber sole-bars with which we are acquainted, there are used eight wrought-iron tubes, 2⅞ inches in diameter, each pair forming one sole-bar, and suitably connected and supported by malleable cast-iron parts. The boldness with which these castings are used in a structure upon which so much depends bears testimony to the superiority of American foundry practice and to the courage of American designers in perhaps about equal proportions. Certainly no Great George Street engineer would venture upon putting annealed castings in such a position; and, if he did, he would, no doubt, meet with disaster. The tube-frame waggons have, however, been largely built and extensively used in America, and we understand from Mr. Jefferds that there is no reason to think that the castings are not suitable for the work.

The interest in the paper, to judge by the channel into which the discussion was turned, did not centre so much in the constructive details of the waggon described as it did upon the general policy of the American as against the English methods of handling railway freight. In the United States, as most people know, they go upon the principle of having large goods waggons, some even as long as 40 feet and capable of carrying 40 tons. These, however, would be of extreme dimensions, the more usual length being 32 to 34 feet, with a carrying capacity of 30 to 32 tons—that is, American tons of 2000 pounds to the ton. These waggons are mounted on a pair of bogies, each having four wheels. Our own goods trucks are something about 20 feet long, and are mounted on wheels with axles which are fixed with their axes parallel to the ends of the trucks. The English truck will carry 10 tons, and weighs, according to Mr. Jefferds, 8 tons. Mr. Jefferds is, however, a little out here. No doubt some 10-ton trucks weigh 8 tons, but Mr. Williamson, of the Great Western Railway, and Mr. T. Hurrey Riches, of the Taff Vale Railway, state the average weight of their 10-ton trucks to be 5 tons 5 hundredweight and 4 tons 17 hundredweight respectively. Still, making every allowance for errors of this nature, and the possibility of Mr. Jefferds having placed his case in the most favourable light, there is no doubt but that the Americans carry their merchandise over their railways with a far lower proportion of tare to paying load than is the case in England. It has been notorious for years that American railway rates are far below those of this country. We will, however, let Mr. Jefferds speak for himself by making selections from his paper, merely first pointing out the great importance of this question upon our national well-being.

The supremacy of Great Britain—indeed her existence as a Power—is founded upon cheap ocean carriage. We can carry goods across the sea at a lower price than any other people.

Were we to lose that advantage to-morrow, a large part of our population would be in want of bread within a few months, and there would hardly be an individual in the country whose wealth and comfort would not be lessened. Railway carriage is of next importance, and it is only our insular position and the small size of the country which renders it secondary. There is an impression, well or ill founded, that railway goods carriage might be conducted with more economy in England; and when an American expert comes to us to show how, in his opinion, an improvement may be made, he is worthy of our best attention.

Mr. Jefferds begins his paper by pointing out that the present build of goods trucks on English railways differs nothing in principle, and but little in construction, from the truck made by George Stevenson to carry the barrel of water required for replenishing the *Rocket's* boiler. This, perhaps, is rather an exaggerated statement, but there is more truth in it than we find it pleasant to acknowledge. In America, however, such vehicles, as we have already said, are no longer seen. "Since 1865, the railway rates of the United States have," the paper says, "been reduced fully 79 per cent.; so that the railways are now rendering for £21 the same service for which in 1865 they charged £100. The reason they have been able to make so great a reduction is that they have gradually improved their goods waggons, which would formerly carry loads of their own weight only, but will now carry three or four times as much. . . . In 1889 the average rate charged for all descriptions of goods on all the railways of the United States, including terminal charges, was only 0·488*d.* per ton mile, while the average cost to the railways was only 0·311*d.* The average dividend on highly inflated shares was 3·3 per cent." Turning to individual instances, Mr. Jefferds selects three prominent American lines—the New York Central, the Pennsylvania, and the Philadelphia and Erie. The working expenses per ton mile on these were 0·28*d.*, 0·201*d.*, and 0·176*d.* respectively. The working expenses per ton mile on our London and North-Western Railway are 0·65*d.* per ton mile, or three times as much as the great American line, the Pennsylvania. When one thinks how many millions two-thirds of the cost of goods carriage in this country amounts to, one begins to grasp the magnitude of the question. According to Mr. Jefferds, all this vast sum may be saved by the use of his carriage, although he only claims a modest 9 per cent. for his particular tube-frames.

The average Englishman often wonders how it is American farmers can send wheat right across the Atlantic and undersell British growers comparatively on the spot, and that more especially since agricultural rents have so gone down that farms can be got at purely nominal rents. Here, however, is a fact, according to Mr. Jefferds's paper, which may help to throw some light on the question:—"At the present time, for every hundred tons of grain he sends to London, a farmer living 1000 miles inland in the United States has an advantage of £30, after paying both land and ocean transit, over a farmer living at Stirling in Scotland, only 420 miles from London."

The benefits promised by Mr. Jefferds, if we use his big bogie waggons, are, indeed, immense, but the price we shall have undoubtedly to pay for these benefits is immense also. In the first place, it would be very difficult—practically, we think, impossible—to run these long waggons in mixed trains with the English trucks. The difficulties are mechanical—the principal one being the system of buffing—but we have not space to enter upon them here. Therefore these long bogies could only be brought in by a very sweeping change. What would this involve? Nearly the whole of the usual appliances on the permanent way would have to be entirely reconstructed. Sidings and platforms would be too short, points would have to be altered, locking bars and switching apparatus would have to be replaced, turntables would be too small, hydraulic hoists not sufficiently powerful, even if large enough, and weighbridges would have to be replaced, coal-tips rebuilt—in fact, English railway lines would want reconstructing so far as the appliances for dealing with goods traffic are concerned.

There is, however, another salient feature to consider before we can take Mr. Jefferds and his big bogies to our bosom.

The goods traffic of America is more in bulk than that of England, as might be expected in comparing a comparatively new and sparsely peopled country with one older and more crowded. A 30- or 40-ton waggon can be loaded at St. Louis, Chicago, or elsewhere, and sent through to New York. The journey is long enough to make a big car worth filling. In Britain the conditions are different. During the discussion, one English railway manager said the average lading of general merchandise on his line was not much above 2 tons; another, Mr. Williamson, of the Great Western Railway, gave 2½ tons as a fair average. Mr. Jefferds retorts to this that no one expects a truck to go with only one parcel; the trucks can be filled even if it takes the goods of twenty consignees to make a load. Here again another question arises—Do the Americans pay for cheapness by delay? In England a merchant or manufacturer expects goods given over to the Company one afternoon to be delivered the next day (perhaps his expectation is not always fulfilled); but in America, we are told, no such expedition is observed. May not this be due to the fact that a big waggon is often waiting for the last hundredweight or two to make up its load?

The fact is, the question wants treating quantitatively, and for this purpose a vast mass of statistics must be accumulated; for Mr. Jefferds has only touched the fringe of the question. The arguments he has advanced are, however, sufficiently powerful to have made out a very strong *primâ facie* case—most distinctly a case for inquiry. The railway authorities of this country are the only persons who can supply the details by means of which the problem can be adequately discussed.

The discussion on Mr. Jefferd's paper occupied the greater part of the two evenings of the meeting. Mr. Addy's paper on milling cutters was, however, read and discussed. The author gave analyses of the steel used for the purpose, which appeared to approximate closely to razor steel, and by means of wall diagrams explained the mechanical principles which he considered should govern the construction of milling tools, and the machines in which they are used. Without the aid of these diagrams it would be impossible to make the subject clear, and for these we must refer our readers to the volume of the Transactions. The discussion which followed the reading of the paper turned chiefly on the speeds of cutting by milling in use respectively in this country and America; the fact that the American machinists are in advance of us in this respect being fully acknowledged by those present.

The next meeting of the Institution will be held in London early next year.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor, the Marquis of Hartington, LL.D., of Trinity College, Lord Walsingham, M.A., of Trinity College, Dr. Morgan, Master of Jesus College, Dr. A. S. Lea, Prof. Browne, Prof. Liveing, Prof. Foster, Albert Pell, M.A., of Trinity College, J. D. Dent, M.A., of Trinity College, W. Aldis Wright, M.A., of Trinity College, L. Ewbank, M.A., of Clare College, F. Whitting, M.A., of King's College, R. F. Scott, M.A., of St. John's College, J. R. Green, M.A., of Trinity College, have been appointed a Syndicate to consider the subject of the letter, dated July 25, 1890, addressed by the President of the Board of Agriculture to His Grace the Chancellor, on the subject of Agricultural Education in the University, and to report to the Senate before the end of the Lent Term, 1891.

At the annual election, on November 3, three Fellowships out of five were awarded to students of Natural Science:—Mr. R. A. Sampson, B. A. (Third Wrangler, 1888, First Smith's Prizeman, 1890), Lecturer in Mathematics at King's College, London, for researches in Hydrodynamics; Mr. L. E. Shore, M.A., M.B., B.C. (First Class Natural Sciences Tripos, 1884–85), (Senior Demonstrator of Physiology in the University, for researches in Physiology; E. H. Hankin, B.A. (First Class Natural Sciences Tripos, 1888–89), Junior George Henry Lewes Student in Physiology, for researches in Bacteriology.

Mr. Walter Heape, M.A., of Trinity College, has been elected to the Balfour Studentship in Animal Morphology, in succession to Mr. William Bateson, Fellow of St. John's College.

Mr. E. E. Sikes, Scholar of St. John's College, has been appointed by the Vice-Chancellor to hold the Newton Studentship at the British School of Archæology in Athens.

The Board for Biology and Geology propose to take power to appoint to the University Table of the Marine Biological

Laboratory at Plymouth, a student of either sex not a member of the University, failing a suitable University applicant.

The proposed new statute affecting the contributions to the University of financially depressed Colleges, passed the Senate on October 30, by 72 votes to 30. The opposition was headed by Prof. Humphry, Prof. Liveing, and Mr. W. N. Shaw. Under the new statute, which has yet to receive the consent of the Queen in Council, depressed Colleges may withhold part of their contribution to the University, and, instead thereof, elect University teachers to Fellowships.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 27.—M. Hermite in the chair.—Observations of the planet Venus at Nice Observatory, by M. Perrotin. (See Our Astronomical Column.)—On the reduction to the canonical form of differential equations for the variation of arbitrary constants in the theory of movements of rotation, by M. O. Callandreau.—The neutral meridian of Jerusalem-Nyanza, proposed by Italy to fix the universal hour, determined by its horary distance from 120 observatories, by M. Tondini. A list is given of the time-intervals of sixteen important observatories from the Jerusalem meridian, which cuts the equator about 75 kilometres east of Lake Nyanza. This list is part of a larger one giving the latitudes and time-intervals of 120 observatories from the same meridian. —On the developments in series of the integrals of certain differential equations, by M. R. Liouville.—Periodic visibility of interference phenomena when the light source is limited, by M. Ch. Fabry.—Thermo-electric researches, by MM. Chassagny and Abraham. It is well known that if thermo-electric couples be formed from three metals, A, B, and C, the electromotive forces obtained at a given temperature in each case may be expressed by the following equation :—

$$E(AC) = E(AB) + E(BC).$$

The authors have found the following results in some researches on this relation :—

Couples.		Electromotive Forces. Calculated.		Observed.
Iron-Copper	...	0·0010925 volt	...	0·0010926 volt.
Iron-Platinum	...	0·0016842 ,,	...	0·0016842 ,,
Copper-Platinum	...	0·0005917 ,,	...	0·0005917 ,,

—Electrolysis of aluminium fluoride by igneous fusion, by M. Adolphe Minet. The author has previously shown that he had produced aluminium by electrolyzing its fluoride. He now describes the composition and properties of the bath used, and the relation between the constants of the current and those of the electrolyte—(1) when the salts which make up the bath are chemically pure ; (2) when the electrolyte is mixed with other salts.—On amylamines, by M. A. Berg.—On the arteries and veins of nerves, by MM. Quénu and Lejars.—On the changes of colour of the common frog (*Rana esculenta*), by M. Abel Dutartre.—On the anatomy of the grasshopper and lizard, by M. Ch. Contejean.—The rot of the heart of the beetroot, by M. Prillieux.—Seismic motions at Chili : earthquakes of May 23, 1890, by M. A. F. Noguès. Of the eighteen movements recorded, five took place during the spring in the southern hemisphere, one in the summer, four in autumn, and eight in winter. Of the six of which the direction of motion has been exactly determined, three had an east to west direction, one south-west to north-east, one from north to south, and one from south to north.—Experiments on sedimentation, by M. J. Thoulet.—Theory of sedimentation, by M. A. Badoureau.

THE CURE OF CONSUMPTION.

WHEN we read the announcement of some fresh scientific discovery, the first impulse, perhaps, is to ask, "Who has made it?" and the second, to say, "Does it sound right?"

The amazing declaration that Prof. Koch had discovered the sure means of arresting the growth of the bacillus of tuberculosis, *i.e.* of "consumption" without further imperilling the lives of its countless victims, must have made many ask themselves these questions, and in all cases probably with unanimously satisfactory replies.

The man who has made this discovery has been known for more than the last decade as the foremost technologist in bacteriology. The discoveries and really infinitely wide generalizations of M. Pasteur had cleared the way and pointed out the broad path of investigation in this branch of pathology. When Dr. Koch began his remarkable research into the life-history of the bacillus of anthrax or splenic fever, the completeness and perspicuity of that work obtained for him the opportunity of devoting his whole energies and time to this department of pure science, and now not only its votaries, but the whole mass of mankind, will applaud the magnificence of what has been achieved by patient toil in a laboratory.

Many of us doubtless remember the eloquent account given by Prof. Tyndall in the *Times*, some eight years ago, of Koch's discovery of the direct cause or virus of consumption, viz. the *Bacillus tuberculosis*, and, possibly, some may remember the ignorant contempt with which this announcement was received by the enemies of science and truth—the anti-vivisectionists. In 1884, Koch published, in his customarily complete manner, the whole chain of his investigations into this, the most general of specific diseases, and it was in this paper that he set at rest, by final judgment and demonstration of the infective character of the disease, a debate of 40 years. On looking back to that time, it is easy to see (in answer to the first question) that the character of the man's work insured, if his health permitted, the accomplishment of a gigantic step forward, such as that which is now announced on the most trustworthy authority. Were we not in eager anticipation of the publication of Dr. Koch's experimental facts, it would be out of place to ask the second question. But, as is well known, the bearing which the general drift of bacteriological research possesses at the present time is, in this connection, of the utmost interest.

Already we have learnt that, as of course seemed necessarily the case, Koch early abandoned the search for an antidote among pharmacopœial remedies, and looked for the means of arresting the functional activity of the bacillus among the biological waste-products of the organism. Pasteur's fundamental discoveries in fermentation had established the law that every micro-organism produces, from the substances which it katalyzes as a result of its biological activity (and especially multiplication), a material or materials, which, on accumulation, inhibit its growth, and finally, indeed, arrest its vitality. The actual discovery that this principle is applicable in its entirety to micro-organisms which are pathogenic, *i.e.* causative of disease, is probably due to M. Charrin, whose investigations into the properties and growth of the *Bacillus pyocyaneus* have shed much light on this difficult area of investigation. But M. Pasteur's teaching has been productive of similar results in other terribly common diseases, notably in diphtheria, at the hands of Drs. Roux and Yersin. In all cases albuminous substances have been found, which, while toxic in certain doses, are nevertheless capable of giving immunity to animals from the disease which produced them. Such albumins, as was first shown by Wooldridge, are not only to be obtained as a result of the specific katalysis of artificial cultures by the pathogenic microbe, but exist already formed in some animal tissues. According to the latest investigations of Hankin in this direction, and according to the observations of Reichert and Weir Mitchell and Wolfenden on snake poisons, and of Martin on anthrax, &c., these toxic, and yet protective albumins seem to belong almost exclusively to the class known as globulins.

Should these generalizations prove to be true, one most important step alone will be gained, viz. a definite advance into the unknown desert of biological chemistry. But, to return to the arrest *intra vitam* of an infective virus, there is another factor in the successful extinction of a parasitic poison, such as the tubercular microbe, and that is the specific resistance of the tissues to their invasion by bacilli, which has been so strikingly elucidated by Metschnikoff and others.

This factor has a specially important bearing in tuberculosis, since the bacillus, as is well known, grows with vastly different rapidity in various individuals, and even in the same patients exhibits great differences of vigour according to the tissue it has attacked. This makes the practical application of Prof. Koch's discovery so much the more striking as well as important. Already it is stated that the most chronic forms of tuberculosis, viz. caries of bones and joints and lupus, yield most readily and rapidly to the preventive treatment, whereas a greater difficulty is experienced in dealing with advanced lung disease.

There are many instructive parallels which might be drawn between this last fruit of experimental science (absurdly called vivisection) and the direct application by M. Pasteur of his labours to the prevention of a far more horrible, if fortunately relatively much rarer, disease—hydrophobia; but the storm of incredulity and abuse with which Pasteur's single-minded labours were received are replaced in the present instance by respectful appreciation and admiration.

It may be that this is a sign of the wider public knowledge of the scientific facts concerning infectious disease, or it may be that the irresistible effect of the truth of M. Pasteur's labours is clearing away the obstruction of ignorance and folly. In either case it is a happy augury of the future. But we fear much of the very different feeling with which this last gift of pure science has been received is a sad testimony to the frightfully wide extent to which this distinctive disease, tuberculosis, prevails, and that really there is no family but feels what a priceless result Prof. Koch has attained if an extended trial should confirm his early successes.

Whatever be the explanation, we earnestly hope that the public interest which is thus awakened in a practical exposition of the extreme importance of supporting scientific research, although its objects may not be at first sight apparent, will receive no disappointment or check, but develop into a true appreciation of the great principles which underlie human happiness, health, and wealth.

CLERK MAXWELL'S PAPERS.

The Scientific Papers of James Clerk Maxwell. 2 Vols. Edited by W. D. Niven, Director of Studies at the Royal Naval College, Greenwich. (London: Cambridge University Press, 1890.)

THE gratitude with which we receive these fine volumes is not unmingled with complaint. During the eleven years which have elapsed since the master left us, the disciples have not been idle, but their work has been deprived, to all appearance unnecessarily, of the assistance which would have been afforded by this collection of his works. However, it behoves us to look forward rather than backward; and no one can doubt that for many years to come earnest students at home and abroad will derive inspiration from Maxwell's writings, and will feel thankful to Mr. Niven and the committee of friends and admirers for the convenient and handsome form in which they are here presented.

Under the modest title of preface, the editor contributes a sketch of Maxwell's life, which will be valued even by those who are acquainted with the larger work of Profs. Lewis Campbell and W. Garnett; and while abstaining from entering at length into a discussion of the relation which Maxwell's work bears historically to that of his predecessors, or attempting to estimate the effect which it had upon the scientific thought of the present day, he points out under the various heads what were the leading advances made.

In the body of the work the editor's additions reduce themselves to a few useful footnotes, placed in square brackets. Doubtless there is some difficulty in knowing where to stop, but the number of these footnotes might, I think, have been increased. For example, the last term in the differential equation of a stream-function symmetrical about an axis is allowed to stand with a wrong sign (vol. i. p. 591), and on the following page the fifth term in the expression for the self-induction of a coil should be $-\frac{1}{3}\pi \operatorname{cosec} 2\theta$, and not $-\frac{1}{3}\pi \cos 2\theta$.

To a large and enterprising group of physicists, Maxwell's name at once suggests electricity, and some, familiar with the great treatise, may be tempted to suppose that this book can contain little that is new to them. It was De Morgan, I think, who remarked that a great work often overshadows too much lesser writings of an author upon the same subject. In the present case it is true that much of the "Dynamical Theory of the Electro-magnetic Field" was subsequently embodied in the separate treatise. Nevertheless, there were important exceptions Among these may be noticed the experimental method of determining the self-induction of a coil of wire in the Wheatstone's balance. By adjustment of resistances, the steady current through the galvanometer in the bridge is reduced to zero; but at the moment of making or breaking battery contact, an instantaneous current passes. From the magnitude of the throw thus observed in comparison with the effect of upsetting the resistance-balance to a known extent, the self-induction can be calculated. The letter to Sir W. Grove, entitled "Experiment in Magneto-electric Induction" (ii. p. 121), will also be read with interest by electricians. It gives the complete theory of what is sometimes called "electric resonance."

There can be little doubt but that posterity will regard as Maxwell's highest achievement in this field his electromagnetic theory of light, whereby optics becomes a department of electrics. The clearest statement of his views will be found in the note appended to the "Direct Comparison of Electro-static with Electro-magnetic Force" (vol. ii. p. 125). Several of the points which were then obscure have been cleared up by recent researches.

Scarcely, if at all, less important than his electrical work was the part taken by Maxwell in the development of the Dynamical Theory of Gases. Even now the difficulties which meet us here are not entirely overcome; but in the whole range of science there is no more beautiful or telling discovery than that gaseous viscosity is the same at all densities. Maxwell anticipated from theory, and afterwards verified experimentally, that the retarding effect of the air upon a body vibrating in a confined space is the same at atmospheric pressure and in the best vacuum of an ordinary air-pump.

Besides the more formal writings, these volumes include several reviews, contributed to NATURE, as well as various lectures and addresses, all abounding in valuable suggestions, and enlivened by humorous touches. Among the most noticeable of these are the address to Section A of the British Association, the lectures on colour vision, on molecules, and on action at a distance, and, one of his last efforts, the Rede Lecture on the telephone. Many of the articles from the "Encyclopædia Britannica" are also of great importance, and become here for the first time readily accessible to foreigners. Under "Constitution of Bodies," ideas are put forward respecting the breaking up of but feebly stable groups of molecules, which, in the hands of Prof. Ewing, seem likely to find important application in the theory of magnetism.

A characteristic of much of Maxwell's writing is his dissatisfaction with purely analytical processes, and the endeavour to find physical interpretations for his formulæ. Sometimes the use of physical ideas is pushed further than strict logic can approve;[1] but those of us who are unable to follow a Sylvester in his analytical flights will be disposed to regard the error with leniency. The truth is that the limitation of human faculties often imposes upon us, as a condition of advance, temporary departure from the standard of strict method. The work of the discoverer may thus precede that of the systematizer; and the division of labour will have its advantage here as well as in other fields.

The reader of these volumes, not already familiarly

[1] "With all possible respect for Prof. Maxwell's great ability, I must own that to deduce purely analytical properties of spherical harmonics, as he has done, from 'Green's theorem' and the 'principle of potential energy,' seems to me a proceeding at variance with sound method, and of the same kind and as reasonable as if one should set about to deduce the binomial theorem from the laws of virtual velocities or make the rule for the extraction of the square root flow as a consequence from Archimedes's law of floating bodies."—Sylvester, *Phil. Mag.*, ii. p. 306, 1876.

acquainted with Maxwell's work, will be astonished at its variety and importance. Would that another ten years' teaching had been allowed us! The premature death of our great physicist was a loss to science that can never be repaired.

RAYLEIGH.

SAP.

Sap: Does it rise from the Roots? By J. A. Reeves. (London: G. Kenning, 1890.)

THE object of this book is clearly stated in the following words from the introduction (p. 4):—

"Facts will be advanced to show there is no evidence to support any of the following theories, viz.:—That the sap in trees rises at any time; that inorganic matter rises from the soil; that the soil is exhausted by the growth of vegetation; that sap is elaborated in the leaves," &c.;

and the style is exemplified in the following quotations from the conclusion (p. 82):—

"Instead of water ascending and gases descending; the facts (which are open to the observation of any person disposed to give unbiassed attention to the subject) go to prove that the water *descends* to the roots, and the gases *ascend* to the leaves, both actions being in strict conformity with the Laws of Gravitation."

"Let the reader witness a monster forest tree during a Summer shower, after a long drought, and then calmly consider—Whether the CREATOR IN HIS INFINITE WISDOM ordained that the thirsty leaves should be refreshed and invigorated by drinking in the genial rain falling upon them. Or,—Whether each leaf was designed to *resist such moisture*, but, at the same time, to draw the water it needs from the soil, which is often hundreds of feet below, and as DRY AS DUST."

The italics and large and small capitals are the author's, and we have now to examine how he proceeds to justify the extraordinary statements quoted.

Starting with a number of extracts from Sachs's "Textbook of Botany," which refer to several different things, and are in part misquoted or mutilated, and of which the most remarkable is as follows,[1] "It is not known how water reaches the tops of trees, but probably by the *formation of dew*," the author concludes that much difference of opinion exists. This conclusion is not without warrant, but the nature of the diverging opinions is by no means illustrated by his statements, and is not to be understood without an acquaintance with much more modern literature than he seems to have any knowledge of. At any rate, he might have obtained even more conflicting statements by judicious culling from the writings of Böhm, Elfving, Westermaier, Vesque, and other modern authorities. Granted, however, that much difference of opinion has been expressed on the subject, let us see how the author proceeds to clear up the matter. He suggests as an alternative theory that the leaves of plants obtain their water and mineral substances from the air.

"It is suggested that the foliage of plants by absorbing the moisture in the air also absorbs the impalpable dust which it contains."

[1] At p. 684 of Sachs's "Text-book," second edition (English translation), this statement runs: "It is not known how this water has reached the higher parts of the trees, though it is possibly by the formation of dew," &c., and it bears a very different signification from that given.

"It seems quite possible that, in dry weather, a portion of the dust alluded to, which comes in contact with the leaves of plants, may, with the dews of night, pass through the leaf-cells into the downward flow of sap. If so, such inorganic matter becomes a constituent of the sap, to be chemically acted upon in the formation of new cells effecting the mysterious operations called growth."

This kind of thing is sufficiently startling, and what its effect may be on the minds of those insufficiently acquainted with the elements of botany need not be discussed. For the information of those who expect to find such views supported by new and adequate evidence, however, the following illustrations may suffice:—

"The oil which rises through the cotton wick of a lamp to support the flame is constantly referred to as an apt illustration of the transpiration theory."

"The leaves of the weed anacharis contain a large proportion of silica, although the plant has no root, and it grows whilst flowing with the stream."

"Seeds sown in flannel, moistened with distilled water, will grow (although not to maturity) and produce as rich green foliage as if grown in alluvial soil. [N.B.—Iron cannot be supplied from flannel.]"

If it were not that the book contains internal evidence of the deadly earnestness of the writer, we should have regarded these (and other paragraphs, adduced to show that the roots do not absorb the water and minerals of the transpiration current) as quaint jokes of the Max O'Rell or Mark Twain type. Moreover, the work teems with such funny statements. Speaking of trees (p. 40),

"If the pendent ends of the branches be embedded in the soil, the descending sap will be *drawn out* and and [*sic*] roots will be formed of the discharged sap."

Although the superfluous "and" might suggest that even the pen of the author gasped and stammered, as it were, at this monstrous statement, we fear it must be regarded as an innocent misprint, for the idea that tissues and roots can be formed by the mere hardening of sap is gravely expressed in several places, *e.g.* pp. 37, 48, and 54.

Other notions of sixteenth century value are to be found serving as the foundation stones for the curious superstructure which the author dignifies as a theory. Thus, on p. 32:—

"The germination and growth of a seed seem to be controlled by the same law of gravitation as the growth of a mature plant. Water *descending*, gas *ascending*. . . . When, however, the seed is placed in moist warm soil, water is absorbed, and a kind of fermentation or decomposition commences, the contents are expanded, the gas is necessarily evolved. This expansive operation continues until the skin of the seed is broken. The heavy watery parts exude first, and cell to cell of atomic matter becomes united with the embryo-radicle, and gravitates downwards, forming the root; while the gases or vapours, which result from the fermentation in the seeds, press upwards and cause the plumule to form."

We could not resist quoting this rather lengthy joke, for the sake of the climax: it may be doubted whether the days of a belief in levitation could have produced a statement to equal the last sentence.

This must suffice to show the tenor of the production before us, and we can only conclude by expressing our wonder that any writer could be found to invent the text and any publisher to produce it.

INDOOR GAMES.

The Hand-book of Games. Vol. I. Table Games. (London: Bell and Sons, 1890.)

THIS work was originally published in the year 1850. In spite of the antiquity of the information, there is a steady demand for the old edition, and the publishers, having resolved to reissue the book, decided that it should be thoroughly revised, and many of the articles entirely re-written. In consequence of the recent development of old games and the invention of new ones, the present edition will fill two volumes of about 500 pages each, while the first edition consisted of only one volume of 600 pages.

The games included in the first volume are known as table games. The first one treated of is billiards, and is written by the noted amateur Major-General A. W. Drayson; the well-known professional Mr. W. J. Peall has read through the proof-sheets, and, in his own words, "endorsed, in nearly every case, the author's advice, both theoretical and practical." Billiards is one of the many games that have made remarkable progress in the last fifty years. Of its origin very little is known: some consider that the French invented it; others that the Germans originated the idea, the French only improving on them. Bouillet gives the English as the originators of it. "Billiards," he says in his first work, "appears to be derived from the game of bowls. It was anciently known in England, where perhaps it was invented. It was brought into France by Louis XIV., whose physician recommended this exercise." In his other work we read, "It would seem that the game was invented in England." Whatever may have been the origin of the game, it was originally played on the floor or on a table, and consisted in trying to send a ball through a ring which revolved on a pin or stick fixed firmly on the floor or table. A few years before 1674, billiards must have been well known, especially in England, for in a work published in that year, where it is described as a "most gentle, cleanly, and ingenious game," the author says that in England there were few towns of note "which had not a public billiard table, neither are they wanting in many noble and private families in the country." From those days up to the present time the game has gradually been raised from the "disreputable to the highly respectable," and it is now ranked among the first-class ones.

The game as described in this article is for amateur players only, and, as stated by Mr. Peall, "there are few amateurs who may not gain some useful hints from a study of this book." Although the author gives some very good explanations of the various strokes, describing the best ways of making them and *the effects* produced on the impact of balls, yet in some cases it would be advantageous to the reader to know the reasonings from which the results are drawn. On pp. 34 and 35, in discussing the effect produced by "side" on the striker's ball, the example he gives serves to illustrate our point.

Following these explanations, the games of pool, black pool (commonly known as "shell out"), pyramids, and snooker are described, the last of which is an extension of the game of pyramids, but not as yet generally known.

We now come to the game of chess, by Mr. R. F. Green, who gives a condensed but capital account of it as it is played to-day. Of all games chess is the most difficult, and in consequence of the riddance of the element of chance, great skill is required to play it well. In the study of this game a great expenditure of time is necessary—in fact, "no knowledge or proficiency, easily acquired, could be held in such high and general esteem; and the time involved may, especially in the case of young students, be looked upon as well spent. It constitutes a mental training of the greatest possible value, and promotes a taste which can only be elevating." Lovers of this game will find much in this article that will interest them, and the hints, technical terms, rules, moves, &c., should form a good foundation for beginners.

The remaining games include draughts, backgammon, dominoes, solitaire, reversi, go-bang, rouge et noir, roulette, E. O., hazard, and faro, all of which are thoroughly explained and illustrated by "Berkeley."

In conclusion, a work of this sort becomes a necessity to those who wish to understand the scientific principles which form the bases of many of our games, while for those who play occasionally it will serve as a most handy book for reference. It is thoroughly to be recommended.

W.

OUR BOOK SHELF.

Elementary Algebra. With numerous Examples. By W. A. Potts, B.A., and W. L. Sargant, B.A. (London: Longmans, Green, and Co., 1890.)

IN this book the principles of algebra as far as quadratic equations only are dealt with. The authors have explained them in plain and simple language, and have worked out numerous examples in order to illustrate the methods adopted. In an elementary treatise like this, intended for those who are preparing for public school entrance examinations, great importance must be attached to the working out, briefly and neatly, of examples, and here we have a good and copious collection, together with some papers set at former entrance examinations.

Heat and Light Problems. By R. Wallace Stewart. University Correspondence College Tutorial Series. (London: W. B. Clive and Co., 1890.)

THIS work forms a supplement to the author's "Elementary Text-book of Heat and Light," and is an expansion of the chapters on calculations in that book. The mathematical sides of both these subjects only being dealt with, the fundamental formulæ in each case are clearly worked out and illustrated by many examples. At the heading of each chapter a short summary is given, for convenience of reference, of the many formulæ that may have been proved in previous chapters, but which are used in the one under consideration. This method causes a saving of time and patience, and facilitates the solving of the problems. Students who find special difficulties with regard to the questions on the quantitative relations of either of these two branches of physical science, cannot do better than study this work. By so doing, they will find themselves very much enlightened, and their difficulties considerably diminished.

Annalen des k.k. naturhistorischen Hofmuseums, Wien, Bd. V., Nr. 2 and 3, 1890.

THE above-named (445 pp. in all) contain six original contributions and notices. Of the former, one, by Dr. Karl Fritsch, is botanical, and deals with the flora of Madagascar; another, by Ludwig Hans Fischer, is devoted to personal adornments among the native Indians;

and, of the four which remain, three are zoological, the fourth, by Dr. Felix Koerber, being meteorological. Dr. Fritsch's communication, *apropos* of collections made by Dr. Paulay on the voyage of the "*Saida*," adds to the genera *Blepharis* and *Walleria* each a new species, while new varieties of *Hibiscus vitifolius* and *Cynorchis fastigiata* are described. Dr. Fischer's paper gives an account of his journeys and collections made on behalf of the Vienna Museum. It is a most interesting and carefully executed work of 30 pp., with six plates and 51 admirable woodcuts. The author's notes on ear ornaments are especially commendable, but when all is done as by him it becomes difficult to particularize. This monograph bears the same stamp of excellence as those of Dr. Otto Finsch and Prof. Hein which have preceded it (cf. NATURE, vol. xlii. p. 157), and ethnologists owe the authorities of the Vienna Museum a debt of gratitude for the manner in which they have enriched the literature of their subject. Of the zoological treatises, one (by Dr. Gottlieb Marktanner-Turneretscher) is a Report upon the Hydroids in the Museum collection. The *Gymnoblastea* and *Calyptoblastea* are chiefly dealt with; several new forms are described, localities and donors' names are sufficiently recorded, and a Report upon the *Hydrocorallines* is promised. The two remaining contributions are entomological. One, by Dr. J. Kreichbaumer (13 pp.), is a continuation of the author's previous Report on the *Ichneumonidæ* in the Museum; new genera and species are described. The other is a lengthy monograph of the Linnean genus *Sphex* (266 pp., with 5 plates) by Franz Friedr. Kohl. The author acknowledges his indebtedness to the collections of other Museums and of private individuals, from many of which types have been lent him, and he makes a point of excepting "the material in the London Museum, which contains the greatest number of types." This is greatly to be regretted, in consideration of the pretentious nature of his work, which purports to be a revisionary monograph of the genus; he promises a companion treatise on the allied genera *Ammophila* and *Sceliphron*, and we sincerely hope that, in preparing this, arrangements may be made whereby he shall consult our national cabinet.

Exercises in Practical Chemistry. By A. D. Hall, M.A. (London: Rivingtons, 1890.)

THE author states in his preface that an opinion has been growing latterly that chemistry, as usually taught, is a subject lacking in educational value, and that this is especially the case inpractical chemistry. These exercises are suitable for boys beginning practical work, and they are intended "to exemplify the exact nature of chemical reactions, and to illustrate some of the great principles and fundamental laws of the science." Consequently many of the exercises are quantitative. The first experiment is a verification of Boyle's law by means of a straight barometer tube and mercury. The second is a determination of the coefficient of expansion of air. After a few such preliminary exercises, the more usual chemical experiments follow. The author has not attempted to give "details of craftmanship," as he states that they can be better obtained from the teacher.

An Elementary Geography of India, Burma, and Ceylon. By Henry F. Blanford, F.R.S. Macmillan's Geographical Series. (London: Macmillan and Co., 1890.)

DR. GEIKIE, the editor of Macmillan's Geographical Series, could not have entrusted the subject of the present volume to a more thoroughly competent writer than Mr. Blanford. In the course of a long service in India, as Mr. Blanford himself notes in the preface, he had occasion to visit most parts of the Empire, so that his knowledge of the geography of India is incomparably more exact, extensive, and vivid than if it had been derived merely from books. Traces of this fact are to be found in every section of his excellent manual. In the preparation of a volume of this kind one of the chief difficulties of the writer is to decide how much shall be omitted; and this question Mr. Blanford seems to us to have settled with admirable tact and judgment. Nothing he introduces would, if properly understood, tend simply to burden the memory. The facts he has selected are both important and interesting; and they are presented in so simple and clear a style, while their relations to one another are so distinctly brought out, that they cannot fail to arrest the attention of young learners, and to foster the growth of individual intelligence. The illustrations—for the most part taken from photographs—are in every way worthy of the text.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Araucaria Cones.

I AM happy to say that I can inform the Duke of Argyll of at least two instances within my own personal observation of the fruiting of Araucaria. The cones were seen, and one of them handled, by myself and many members of the Geologists' Association five years ago, when we were entertained at luncheon by our excellent Rural Dean, the Rev. J. T. Brown, Rector of St. Paul's, Wokingham. The fact will be found recorded in the Proc. Geol. Assoc., vol. ix. p. 223. The other instance was a few years earlier, and the tree which bore the cones is, I believe, still standing on the lawn of Sandhurst Rectory. My attention was drawn to them, as to something somewhat rare, by the present Bishop Suffragan of Reading, who was Rector of Sandhurst at that time. A year or so later, a geologist, who has written much on palæobotany, when on a visit to this neighbourhood for the purpose of making the acquaintance of the London Bagshots, had the assurance to inform me that the Araucaria never blossomed or fruited in this country, because it was a diœcious tree! In order to convince him of his error on so fundamental a matter, I took him to Sandhurst Rectory and pointed out the tree to him; but I cannot recollect if any fruit-cones were on it then.

I may add that the fruit is large and the bract-scales very succulent. It resembles most nearly the fruit of the Alpine cedar (*Pinus Cembra*), but the fruit is three or four times as large.

Wellington College, Berks, Nov. 7. A. IRVING.

IT is quite a common occurrence for the Araucaria to bear cones in this country, when the tree is healthy and of fair size. Very possibly it may be necessary that some check to its development shall have taken place before a large number of cones are formed, as I have never seen more than three or four upon a single tree.

Not only are the cones formed, but seed is ripened, and I have now in my possession some plants about three years old, which I have reared from English-grown seeds picked up under a fruited Araucaria. Apparently about a year elapses between the appearance of the cone and the shedding of the seed, and no doubt towards the end of the summer of 1891 the tree belonging to the Duke of Argyll will yield many thousands of fertile seeds. These do not seem to keep well through the winter, but are best sown in the autumn without delay. Artificial heat is not necessary to their germination. JOHN I. PLUMMER.

8 Constitution Hill, Ipswich, November 11.

IN reply to the Duke of Argyll's inquiries (NATURE, November 6, p. 8), we have an Araucaria in our garden, now about 20 feet high, which bore barren cones first in the summer of 1889. We have also a seedling Araucaria, one of several grown from seeds from large seed-bearing cones gathered from the avenue of Araucarias in the late Lady Rolle's grounds at Bicton Park, near Budleigh Salterton, in 1878, at which time they were abundant on the splendid trees forming the avenue.

Further Barton, Cirencester, Nov. 9. E. BROWN.

Squeaking Sand *versus* Musical Sand.

ALLOW me to use your columns to thank Mr. Henry C. Hyndman for the reference in NATURE of October 2 (vol. xlii. p. 554) to a locality of sonorous sand in the interior of South Africa. Its occurrence in the interior is new to me, though it has been reported from the west coast at Liberia, and at Cape Ledo, from which latter place my friend, Mr. L. Harold Jacoby, a member of the American Eclipse Expedition, recently brought me specimens.

Dr. Alexis A. Julien and myself quite agree with Mr. Carus-Wilson in his remarks (NATURE, October 9, vol. xlii. p. 568) that there is no scarcity of sonorous sand, and only observers are lacking. This we established in 1884, when we announced at once seventy-four localities on the Atlantic coast of the United States, although at the time we began our researches its occurrence at Manchester, Massachusetts, was thought to be unique in America. The localities were in part reported by the keepers of life-saving stations to whom we had sent circulars.

The old theory adopted by Mr. Carus-Wilson, that the sounds are produced by "rubbing together of millions of clean sand grains very uniform in size," is, we think, insufficient to explain *musical* sand, but well adapted to explain *squeaking* sand. Two distinct classes of sounds are produced by disturbing sand, both undoubtedly due to vibrations; the more common sound is caused by attrition of the particles, and has a well-known harsh character by no means musical; this in rare cases becomes a loud squeak. The second is caused, we believe, by oscillations of the particles themselves protected from actual contact by elastic air-cushions, and this is decidedly musical in tone. Musical sand yields notes by friction only when *dry*; squeaking sand yields a harsh, shrill squeak (reminding one of the cry of a guinea-fowl), best when *moist*. This latter variety is very rare; we have collected by correspondence and in person over 500 samples of sand from around the world, and musical sand seems to be comparatively common, but only two localities of squeaking sand are known to us, both in so-called boiling springs—one in Maine, and the other in Kansas. A very small quantity of squeaking sand pressed between the thumb and forefinger produces, when wet, a peculiar shrill squeak—a phenomenon which we think well explained by the attrition theory. The magnificent acoustic displays which I have witnessed in the desert of Sinai (NATURE, vol. xxxix. p. 607) and on the coast of Kauai (NATURE, vol. xlii. p. 389) are, however, manifestly due to greater freedom of oscillatory motion than is possible if the particles merely scrape against each other.

Dr. Julien and I await with interest the second edition of Mr. Carus-Wilson's paper, and shall be very much obliged to him for giving a large circulation to the results we have obtained by extended travel and years of study, though we had planned to present the results to the scientific public in our own way.

Honeycomb Appearance of Water.

THIS afternoon, while ascending a mountain pathway adown which water was trickling, after the torrents of rain that fell in the morning had ceased, I observed an appearance of the surface of running water so exactly like the hexagons of the bees' cells that I looked at it carefully for some time. Little air-bells of water seemed to issue from under the withered leaves lying in the tract, which rushed towards the hexagons, occupying an irregular space about four inches by five. As soon as these air-bells arrived at the hexagons, they arranged themselves into new cells, making up, apparently, for the loss occasioned by the continual bursting here and there of the cell-walls. No sooner had these cell-walls burst, than others closed in and took their places. The worst-formed hexagons were those at the under or lower side of the surface—the part of the surface farthest down the hill; here they were larger, and more like circles. By an ingenious mechanical theory, Darwin accounts for the hexagonal structures of the cells of the hive-bee so as to supersede the necessity of supposing that the hive-bee constructed its comb as if it were a mathematician. But here the blind forces of Nature, under peculiar conditions, had presented an appearance, on running water less than half an inch in depth, so entirely like the surface of a honeycomb, that it would be a startling result could it be reproduced in a laboratory.

On the Soaring of Birds.

MR. GUTHRIE has suggested (November 6, p. 8) one more *vera causa* of soaring. Like all its predecessors, this seems to the last degree unlikely to occur to an extent adequate to the explanation of soaring in the sense in which the term is commonly used, viz. floating at a constant height without motion of the wings.

May not the true cause be that birds do not soar at all in this sense, but only seem to soar because the movement of the wings is too rapid for our imperfect eyes to detect? Is it not possible that birds which to our eyes seem to soar would betray themselves to the camera? Is it not also possible that in some cases the motion may be too rapid to be discovered even by photography?

Whether this be the whole truth or not, I venture to protest against such statements as that a bird followed a ship for 11 minutes "without flapping a wing." If Mr. Guthrie had said, "without any flapping which my eyes could perceive," I should not have had a word of criticism to offer. But that would be an entirely different statement. What would be thought of one who should say that he had seen a conjurer with hands a yard apart take a card with the right hand out of the left without any movement of either hand? Yet many people have seen or seemed to see this common trick.

A Bright Green Meteor.

AN exceedingly bright green meteor was seen here on the 8th inst. at 5.30 p.m. It passed from north to south under α and β Aries, which would give it an altitude of 19°. The path was parallel to the above stars and about 5° in length. This indication may serve to determine the height of the meteor if it was seen from elsewhere.

Weighing by a Ternary Series of Weights.

IT has been shown in NATURE (vol. xlii. p. 568) that any number of pounds may be weighed with weights, the numbers of pounds in which form a geometrical progression with 1 for first term and 3 for common ratio. The following method of treating the same problem may serve to illustrate some remarks made by the President of the Mathematical Section of the British Association at the recent meeting in Leeds. One of these remarks had reference to the fascinating interest attaching to such inquiries into the properties of series of numbers, another showed that the adoption of special systems of notation for different problems was often of great service, and a third remark alluded to the attainment of one and the same result by diverse methods of procedure. In the present case the interest attaching to the subject may be left to speak for itself; the notation suitable for the problem requires elucidation. It is well known that by means of only two figures, 1 and 0, any number may be expressed if we agree that the value of the 1 shall be doubled every time it is removed one place further to the left, so that, for example, 11111 would denote the number $1+2+4+8+16$, and that any number not greater than 31 would be denoted by means of five figures or less. It follows that if we had five weights of corresponding value to the above five numbers we could weigh any number of units of weight from 1 to 31. Now, the present problem only differs from this in two respects—namely, in that the 1 increases threefold in value on being removed one place to the left, and that the value denoted by it may in any position, except the place on the extreme left, be taken negatively. Let us agree to denote the negative value by using a different type, and we may then indicate all values from 1 to 40 as follows:—

1	1	1**11**	5	1**111**	14	10**11**	23	11**11**	32
1**1**	2	1**1**0	6	1**11**0	15	10**1**0	24	11**1**0	33
10	3	1**1**1	7	1**11**1	16	10**1**1	25	11**1**1	34
11	4	10**1**	8	1**1**0**1**	17	100**1**	26	110**1**	35
		100	9	1**1**00	18	1000	27	1100	36
		101	10	1**1**01	19	1001	28	1101	37
		11**1**	11	1**1**1**1**	20	101**1**	29	111**1**	38
		110	12	1**1**10	21	1010	30	1110	39
		111	13	1**1**11	22	1011	31	1111	40

In the extreme right-hand column of this table, where 1 denotes a single unit, the figures 1, **1**, 0 are written each once and then repeated in the same order, and so on to the end. In the second column, where 1 denotes three units, each figure is repeated three times, and then again three times, and so on to the end, but this column begins at the value $\frac{3+1}{2}$. The third column, where 1 denotes nine units, begins at the value $\frac{9+1}{2}$, and the figures are repeated nine times. The fourth column, in which 1 stands for 27, begins at the value $\frac{27+1}{2}$, and contains only the figure 1, twenty-seven times repeated. Hence it will be found that, in order to weigh all the pounds from one to forty, we shall have to make use of *each* weight twenty-seven times.

If, instead of four, seven weights were used, we might, by using each weight $3^6 = 729$ times, weigh any number of pounds from 1 to $729 + \frac{729-1}{2} = 1093$[1] pounds.

Further, we may, for any given number of weights, construct tables, one for each weight, showing the numbers of pounds for which it will be used positively, and also indicating by different type the numbers for which it has to be subtracted. Thus, with five weights we should have for the first four the following tables, whilst the fifth would contain the 81 consecutive numbers beginning with 41 and ending with 121, all to be used positively.

1	4	7	10	13	16	19	22	25
28	31	34	37	40	43	46	49	52
55	58	61	64	67	70	73	76	79
82	85	88	91	94	97	100	103	106
109	112	115	118	121	**2**	**5**	**8**	**11**
14	**17**	**20**	**23**	**26**	**29**	**32**	**35**	**38**
41	**44**	**47**	**50**	**53**	**56**	**59**	**62**	**65**
68	**71**	**74**	**77**	**80**	**83**	**86**	**89**	**92**

5	6	7	8	9	10	11	12	13
32	33	34	35	36	37	38	39	40
59	60	61	62	63	64	65	66	67
86	87	88	89	90	91	92	93	94
113	114	115	116	117	118	119	120	121
14	**15**	**16**	**17**	**18**	**19**	**20**	**21**	**22**
41	**42**	**43**	**44**	**45**	**46**	**47**	**48**	**49**
68	**69**	**70**	**71**	**72**	**73**	**74**	**75**	**76**
95	**96**	**97**	**98**	**99**	**100**	**101**	**102**	**103**

14	15	16	17	18	19	20	21	22
23	24	25	26	27	28	29	30	31
32	33	34	35	26	37	38	39	40
95	96	97	98	99	100	101	102	103
104	105	106	107	108	109	110	111	112
113	114	115	116	117	118	119	120	121
41	**42**	**43**	**44**	**45**	**46**	**47**	**48**	**49**
50	**51**	**52**	**53**	**54**	**55**	**56**	**57**	**58**
59	**60**	**61**	**62**	**63**	**64**	**65**	**66**	**67**

Supposing, now, we wished to determine how any number of pounds, less than 122, may be weighed by means of the weights 1, 3, 9, 27, 81, we seek the number in question, say, for example, 115, first in the upper part of each of the first four tables, as well as in the fifth, and find in this way that we shall require to place all the weights except the weight 3 on one side of the balance; and as the same number is found in thick type in the second table, we see that the weight 3 must be placed in the opposite scale of the balance, and we have $1 + 9 + 27 + 81 - 3 = 115$. In like manner $70 = 1 + 81 - (3 + 9)$ and $38 = 3 + 9 + 27 - 1$. It is manifest that these tables, like the similar tables founded on the binary series, 1, 2, 4, &c., may be used to discover what number up to a certain limit a person has thought of, on being informed first in which of the tables the number occurs in the upper part of the table, and then in which, if any, of the remaining tables it is found in the lower part. For this purpose it is only necessary to add together, not the lowest numbers at the head of the tables, as for the binary series, but to take in each table a number one less than the double of the lowest number, both in the positive and in the negative group, and then to subtract the second sum from the first.

Many facts respecting such tables as the above may be ascertained from the following rows of numbers, which are formed, a column at a time, beginning on the left with 1, 0, 1, and adding the last number to each of the former two, which gives 2, 1 and their sum, 3, for the second column; from these 3 + 2, 3 + 1, and their sum, for the third, and so on.

1 .	2 .	5 .	14 .	41 .	122 .	365 .	1094
0 .	1 .	4 .	13 .	40 .	121 .	364 .	1093
1 .	3 .	9 .	27 .	81 .	243 .	729 .	2187

The upper row contains the lowest numbers in the several tables; the middle number in any column shows the highest number of units that can be weighed with the weights shown in the last row as far as the preceding column. The first two rows, moreover, show, in reverse order, how many times each weight will be used positively or negatively. The *highest* of the weights, for example, will be used only positively, as shown by the numbers 1, 0 in the *first* column, the weight next to the highest will be used twice as often positively as negatively, as shown by the numbers 2, 1 in the *second* column, and so on. Thus, for five weights we should have in the *first* table, as shown by the *fifth* column, 41 numbers in the upper part of the table, 40 in the lower part; in the second table the corresponding numbers are 3 × 14 and 3 × 13; in the third 9 × 5 and 9 × 4, and in the fourth 2 × 27 and 27, as we have already found above.

J. WILLIS.

Bradford, October 22.

[1] The coincidence of this number with the number of NATURE in which this subject was introduced is, of course, purely fortuitous.

THE CELL THEORY, PAST AND PRESENT.[1]

II.

THE continued investigations into the structure of cells, both in plants and animals, led to modifications in the conception of their morphology. Hugo von Mohl announced that he had discovered (*Botanische Zeitung*, translated by A. Henfrey in Taylor's "Scientific Memoirs," vol. iv., 1846) in the vegetable cell, after being acted on by alcohol and iodine, a thin nitrogenous membrane distinct from and applied to the inner surface of the cellulose wall of the cell, which he named the *primordial utricle.* He regarded it as forming a vesicle within the cell wall, and containing the contents and the nucleus. By subsequent observers it has been shown that the primordial utricle is nothing more than a thin layer of protoplasm lying close to the cellulose wall, and inclosing the sap cavity of the cell.

Prof. Huxley, in an article on the cell theory (*British and Foreign Medico-Chirurgical Review*, October 1853), criticized the views of Schleiden and Schwann, and introduced the terms *endoplast* and *periplast* into histological description. He regarded the primordial utricle as the essential part of the endoplast in the plant, and as homologous with the "nucleus" of the animal cell; whilst the protoplasm and nucleus are simply its subordinate modifications. The periplast, on the other hand, consisted in plants of the cellulose cell wall; whilst in animals the cell wall and matrix of cartilage, the cell walls and intercellular substance of connective tissue, the calcified matrix of bone, and the sarcous elements of muscular fibre, were all examples of periplast which had passed through various forms of chemical and morphological differentiation. Huxley maintained that the periplast was the metamorphic element of the tissues, and by its differentiation every variety of tissue was produced, owing to intimate molecular changes in its own substance. The endoplast again might grow and divide, as in the process of cell multiplication; but it frequently disappeared, and underwent neither chemical nor morphological metamorphosis; and so far from being a centre of vital activity, he held that it exercised no attractive, metamorphic, or metabolic force upon the periplast.

[1] The Inaugural Address delivered to the Scottish Microscopical Society, by Sir William Turner, F.R.SS. L. and E., President of the Society. Continued from p. 15.

But about this time it began to be more distinctly recognized that many anatomical units which were to be regarded as cells, as Schwann had indeed admitted in a few exceptional cases, possessed no cell wall or investing membrane, and that the analogy with a bladder or vesicle could no longer be sustained. Thus in 1856 (" Lehrbuch der Histologie," 1857; preface dated October 1856), Leydig gave as his idea of a cell a more or less soft substance, approaching in its original state to the globular in form, which inclosed a central body, the nucleus. Subsequently, the cell substance might harden into a more or less independent membrane, and the cell would then consist of membrane, contents, and nucleus. Leydig's conception, therefore, of what were the essential parts of a cell closely corresponded with the opinion expressed some years previously by John Simon. Brücke again maintained (" Elementarorganismen," *Wien. Sitzbericht*, 1861) that the constancy of the presence of a nucleus was subject to certain limitations, especially in the cells of cryptogams, and that there was no positive information either respecting the origin or the function of the nucleus. He further showed that the soft contents of the cell were of a highly complicated nature, and that they frequently exhibited spontaneous movements and contractility. In 1861 and also in 1863, Max Schultze published (*Müller's Archiv*, 1861, p. 1; " Das Protoplasma," Leipzig 1863), most important papers on the properties of cells. He adopted the term protoplasm which Von Mohl had employed to designate the contents in vegetable cells which surround the nucleus, and applied it to the substance which had the corresponding position in animal cells. He completely discarded the view that a membrane was essential to a cell, and defined a cell as a nucleated mass of protoplasm. He identified the protoplasm of the animal and vegetable cell as essentially the same substance as the contractile sarcode which forms the freely moving pseudopodia of the Rhizopoda, and he looked upon it as possessing great physiological activity. The conception of the functions and relative importance of the constituent parts of a cell had now undergone a material change. The suggestive ideas of Simon and Leydig had been distinctly formulated by Max Schultze. Instead of the cell membrane being regarded as a necessary part of a cell, and the active element concerned in the formation of the cell contents, as Schwann believed, it now became universally recognized as only a secondary structure formed by a differentiation of the superficial part of the protoplasm. Schultze also maintained that the appearance of the membrane might be looked upon as a sign of commencing loss of activity, for a cell with a membrane can no longer divide as a whole, but the division is restricted to the protoplasm contained within it. A cell with a membrane is, he says, like an encysted Infusorian. Taking the embryonal cell as a type, he believed that both the nucleus and the protoplasm were derived from the corresponding constituents of another cell. The protoplasm was the substance especially endowed with living force; the nucleus, he thought, played an important *rôle*, though its exact function could not be defined. The only structural character which Schultze recognized in the protoplasm was a finely granular appearance throughout the somewhat jelly-like, contractile material in which the granules were embedded. Although the name of protoplasm was now given to this substance, yet it obviously corresponded morphologically with the blastema which both Schleiden and Schwann had recognized within the cell, between the nucleus and the cell wall; though it now assumed in the minds of observers a different physiological import.

The reign of protoplasm had now been inaugurated. Not only was the cell membrane believed to be a product of its differentiation, but the matrix of cartilage and of connective tissues, and the other intercellular substances, were thought to be produced not as a secretion, but by a conversion of the protoplasm of the cells into their respective forms. But, further, Max Schultze (" Organis. der Polythalamien," 1854) described a non-nucleated Amœba; and Haeckel (*Zeitsch. f. wiss. Zool.*, 1865, Bd. xv.) and Cienkowski (Max Schultze, *Archiv*, 1865) other non-nucleated organisms, simple in their structure. These organisms were believed to consist solely of a clump of soft protoplasm, which might either be naked, when they were called *simple cytodes;* or encased in a wall or envelope, and then termed *encased cytodes.* Haeckel named these—the most simple of all organisms—Monera, and referred them to a group on the confines of both the animal and the vegetable kingdoms, which he termed Protistæ. Stricker (" Allgemeines über die Zelle," in " Handbuch der Lehre von den Geweben," Leipzig, 1871) also excluded the nucleus as necessary to our conception of an elementary organism. He went so far as to say that the historic name of cell might be applied to the morphological elements of the higher animals, or to independent living organisms, even if they were only little masses of animal sarcode or protoplasm. He was not, however, disposed to extend the definition to isolated fragments of living protoplasm, unless the whole group of phenomena characteristic of an independent organism could be recognized. Stricker held that protoplasm may be fluid, solid, or gelatinous. It exhibited the phenomena of movement, of nutrition, of growth, and the capability of reproducing its like, *i.e.* the sum of the phenomena which are characteristic of living organisms.

The doctrine that a nucleated mass of protoplasm was the structural unit common to organisms generally, both plants and animals—though at the very bottom of the scale the phenomena of life could be manifested by a particle of protoplasm without a nucleus—received its most popular expression, in this country at least, in a well-known address by Prof. Huxley.[1] In this address he stated that protoplasm, simple or nucleated, is the formal basis of all life, and that all living forms are fundamentally of one character. His views, therefore, had undergone some modification, as to the element of the tissue in which vital activity was more especially centred, since the publication of his previous article on the cell theory.

But contemporaneous with these researches on the protoplasmic theory of cell structure and activity, an English physiologist, Dr. Lionel Beale, was conducting investigations into the structure of the simple tissues from an independent and somewhat different point of view. He considered that the elementary tissues of every living being consisted of matter in two states (" Structure of the Simple Tissues," London, 1861)—the one an active, living, growing substance, composed of spherical particles, capable of multiplying itself, and coloured red by carmine, which he named *germinal matter;* the other, named by him *formed material*, was situated peripherally to the germinal matter from which it was produced; it was passive, non-living or dead, incapable of multiplying itself, and not coloured red by carmine like the germinal matter. In adapting these terms to the ordinary nomenclature of the cell, Dr. Beale states:—

" In some cases the germinal matter corresponds to the 'nucleus'; in others, to the 'nucleus and cell contents'; in others, to the matter lying between the 'cell wall,' and certain of the 'cell contents'; while the formed material in some cases corresponds exactly to the 'cell wall' only; in others, to the 'cell wall and part of the cell contents'; in others, to the 'intercellular substance'; and, in other instances, to the fluid or viscid material which separates the several 'cells, nuclei, or corpuscles' from eachother."

According to this theory of the tissues, all the elementary parts of the body consist of two substances—an

[1] " On the Physical Basis of Life," a Lay Sermon delivered November 8 1868, *Fortnightly Review;* also in " Lay Sermons and Addresses," London, 1870.

active, living, germinal matter, an inactive, non-living, formed material. Every living elementary part is derived from a pre-existing living elementary particle. The nuclei of the germinal matter, though remaining for a long time, perhaps, in a comparatively quiescent state, may become active and give rise to new nuclei. Dr. Beale held that the cell wall was by no means constantly present in cells, and that, when present, both it and the intercellular substance were formed or produced by, or a conversion of, the germinal matter. In a subsequent work, Beale ("Bioplasm," London, 1872) substituted the term *bioplasm* for germinal matter, and included in it the nucleus, nucleolus, and some forms of protoplasm. It is, he says, from the bioplasm that the formed material is produced.

An important advance was made in the conception of the structure of the constituent parts of the cell when it was ascertained that protoplasm was not the structureless, granulated jelly, or slime, which it was originally supposed to be, but that it consisted of two parts, viz. a minute network of very delicate fibrils and an apparently homogeneous substance which occupied the interstices of the network. Stilling and Max Schultze recognized the fibrillated character of the protoplasm of nerve cells and axial cylinders, but Frommann, Heitzmann, Klein, and other histologists applied the observations to the structure of protoplasm generally.

The subject made yet a greater step forwards when it was ascertained by Strasburger and Flemming that the nucleus in its passive or resting stage consists, in addition to the nucleolus, of threads or fibres, some finer, others coarser, formed of *nuclein*, and arranged in a reticular network, so as to form little knots at the points of intersection of the fibres. In the interstices of the network an apparently structureless intermediate substance, nuclear fluid or *nucleoplasm*, is situated; and the nucleus is surrounded by a membrane.[1] By some observers the threads are regarded not as forming a network, but as a greatly coiled single thread. From the affinity which they have for colouring-matter, so that they easily stain with dye, Flemming has named them *chromatin fibres*.[2] But the whole question of the relation of the nucleus to the life of the cell, more especially in connection with the production of young cells, assumed a much more definite form when it was discovered that the chromatin nuclear fibres took a primary part in the division of the nucleus in the process of cell multiplication. The nucleus was now reinstated in its place as of primary importance in the structure of cells, and as an essential factor in the formation of new cells. The movements of the fibres within the nucleus, and their rearrangement so as to form definite figures, which changes precede the act of division, were named by Schleicher *karyokinesis*,[3] or nuclear movement, a term which has now been generally adopted.

Waldeyer states that Schneider, of Breslau, was the first to recognize these movements of the nuclear fibres, and to describe them in connection with the division of the ova, the sperm cells, and also the tissue cells of a flat worm, *Mesostomum*; but Bütschli and Foli made the process more generally known. The publication of their researches excited the greatest interest, and a host of observers, amongst whom I may especially name Strasburger, Flemming, Hertwig, Balbiani, E. van Beneden, Johow, Heuser, Pfitzner, J. M. Macfarlane, Carnoy, and Rabl, demonstrated the process in a number of plants and animals, and the literature of the subject is now very extensive. In order to express the appearances presented, and the changes which take place both in the nucleus and in the cell in the process of division, a new nomenclature has been introduced, and we now read of cytaster, monaster, dyaster, equatorial plate and crown, pithode or cask-shaped, spindles, ellipsoids, coils, skeins both compact and loose, pole radiations, spirem, and other terms. From the range of the literature it would be a work of considerable labour and time to make an analysis of the different observations so as to associate with the name of each observer the particular set of facts or opinions which he has made known. Fortunately, this is unnecessary on my part, as admirable *résumés* of the whole subject have recently been published both by Prof. McKendrick of Glasgow (Proc. Phil. Soc., vol. xix., Glasgow, 1888) and Prof. Waldeyer of Berlin (*Archiv für Mikros. Anat.*, Bd. xxxii., 1888).

[1] This membrane is perhaps nothing more than a somewhat differentiated layer of the protoplasm of the cell arranged around the nucleus.

[2] The chromatin fibres appear to be composed of granules or spherules, named "microsome-disks" by Strasburger.

[3] Flemming proposed the term *karyomitosis*, or nuclear threads, to express the thread-like figures formed in the process. M. Carnoy gives the name *enchylema* to the apparently structureless material which occupies the interstices of the network in both the nucleus and cell protoplasm.

Without entering into a detailed description, it may be sufficient for my present purpose to say that four stages may be recognized in connection with nuclear division.

The *first*, or *spirem stage*, exhibits several phases. At its commencement the finer threads, which connect the primary or coarser chromatin fibres of the resting nucleus together, and which give the network-like character, have disappeared along with the knots at their points of intersection and the nucleoli. The primary chromatin fibres, or *chromosome* as Waldeyer calls them, form a complex coil, the spirem or ball of thread, which divides into loops, about twenty in number, and forms a compact skein. The loops are placed with their apices around a clear space called by Rabl the "polar field," whilst their free ends reach the opposite surface of the nucleus or the "antipole." The nucleus also increases in size contemporaneously. The loops next become not so tightly coiled, and form the loose skein though the individual fibres thicken and shorten. A most important change then occurs, which was discovered by Flemming, and which consists in a longitudinal splitting of each loop or primary chromatin fibre into two daughter threads. A spindle-shaped figure, first seen by Kowalevsky, next appears in the nucleus; it consists of threads that stain much more feebly than the chromatin fibres.[1] The spindle has two poles and an equator, and it finally occupies a position in the deeper part of the nucleus; its equator lies in the plane through which division of the nucleus is about to occur. The loops of chromatin fibres group themselves in a ring-like manner around the equator of the spindle with their angles inwards, whilst from each pole of the spindle a radiated appearance (*cytaster*) extends into the protoplasm of the cell. The membrane of the nucleus has now disappeared, so that it is directly invested by the protoplasm of the cell; and it is possible, as Strasburger thinks, that there may be a direct flow of the protoplasm into the nucleus, and that the spindle may be produced by it. At the pole of the spindle, from the point at which the cytaster radiates, E. van Beneden has seen a small, shining, polar body, which Strasburger says is not found in vegetable cells.

The *second*, or *monaster stage*. When the chromatin loops have arranged themselves about the equatorial plane of the spindle with their limbs pointing outwards, and the angle of the loop towards the centre of the spindle, a single star-like figure (*monaster*, *equatorial plate* or *crown*) is produced. The two daughter threads, into which each primary chromatin thread had previously split longitudinally, now separate from each other, and, according to Van Beneden and Heuser, pass to opposite poles of the nuclear spindle, where they form loops. These changes are known as the process of *metakinesis*.

In the *third*, or *dyaster stage*, the chromatin loops at each pole of the spindle arrange themselves so that the angles of the loops, though not touching each other, are close together at the pole, and the limbs of the loops are bent towards the equator of the spindle. Two stars are thus produced (*dyaster*), one at each pole, and each star

[1] Owing to the feeble staining of the spindle figure and of the nucleoplasm, the substances which compose them have been named *achromatin*.

is formed of one of the daughter threads into which each chromatin fibre of the monaster divides by its longitudinal splitting. Each star is sometimes called a daughter skein; around each daughter skein a membrane appears at this stage, and a daughter nucleus is then formed.

In the *fourth* or *dispirem stage*, the chromatin threads thicken and shorten, and the loops of each star arrange themselves with the angles towards the polar field of the nucleus, and the limbs to the antipole.

The division of the mother cell into two new daughter cells is now completed by the cell protoplasm gradually constricting in the equatorial plane until at last it is cleft in twain, and each daughter nucleus is invested by its own mass of protoplasm. The chromatin threads of the daughter skein then form a network of coarser and finer fibres, a nucleolus appears, and the resting nucleus of the daughter cell is completed. Two daughter cells have thus arisen, each of which possesses its own independent vitality. Owing to the very remarkable longitudinal splitting of the fibres of the chromosome, and the distribution of the daughter threads from each fibre to the opposite poles of the spindle, it follows that each daughter nucleus contains about one-half of each chromatin fibre, so that whatever be the properties of the chromosome of the mother cell, they are distributed almost equally between the nuclei of the two daughter cells. As regards the cleavage of the protoplasm, there is no evidence that such a rearrangement of its constituent parts takes place as to give to each daughter cell one-half of the protoplasm from each pole of the mother cell. It is probable that each daughter nucleus simply becomes invested by that portion of protoplasm which lies in proximity to it at the time when the constriction of the protoplasm begins. The young daughter cell, seeing that it is composed both in its nucleus and protoplasm of a portion of each of these constituent parts of the mother cell, possesses therefore properties derived from them both.[1]

Owing to the disappearance of the nuclear membrane at the end of the spirem stage of karyokinesis, at least in cells generally (though it is said to persist in the Protozoa during the whole process of karyokinesis), it follows that the nucleoplasma and the cell protoplasm cease for a time to be separated from each other, and an interchange of material may take place between them in opposite directions—both from the protoplasm to the nucleus, as Strasburger contends, and from the nucleus to the protoplasm, as has in addition been urged by M. Carnoy. In every case it should be remembered that the nucleus, being surrounded by protoplasm, can only obtain its nutrition through the intermediation of that substance, and thus there is always a possibility of the protoplasm acting on the nucleus, and in so far modifying it.

Having now sketched the progress of knowledge of the structure of cells and their mode of production, I may, in the next instance, state the present position of the subject. We have seen that the original conception of a cell was a minute, microscopic box, chamber, bladder, or vesicle, with a definite wall, and with more or less fluid contents. This conception was primarily based upon the study of the structure of vegetable tissue; and, as regards that tissue, it holds good to a large extent to the present day. For the cellulose walls of the cells of plants, with their various modifications in thickness, markings, and chemical composition, constitute the most obvious structures to be seen in the microscopic examination of vegetable tissue. Within these chambers is situated the active, moving protoplasm of the cell, and in it the nucleus is embedded; the cell also contains the sap, crystals, starch granules, or other secondary products. The cell wall is to all appearance produced by a conversion of, or secretion from, the protoplasm. But even in plants a cell wall is not of necessity always present; for, in the development of the daughter cells within a pollen mother cell, there is a stage in which the daughter cell consists only of a nucleated mass of protoplasm, prior to the formation of a cell wall around it by the differentiation of the peripheral part of its protoplasm. Again, the so-called non-cellular plants or Myxomycetes, before they develop their spores,[1] consist of masses of naked protoplasm, on the exterior of which, in the course of time, a membrane of cell wall is differentiated; in the substance of these masses of protoplasm numerous nuclei are situated.[2]

In animal tissues the fat cell possesses a characteristic vesicular form, with a definite cell wall, but neither in it nor in the vegetable cells does the cell wall exercise any influence on the secretion either of cell contents or of matters that are to be excreted. In animal cells a cell wall is frequently either non-existent, or doubtful, and when present is a membrane of extreme thinness. Animal cells, therefore, do not have as a rule the chamber-like form or vesicular character of vegetable cells.

The other constituents of the cell, and the only essential constituents, are the nucleus and the material immediately surrounding it, in which the nucleus is embedded. It is of secondary importance whether this material be called protoplasm, or bioplasm, or germinal matter. The term protoplasm, however, is that which has received most acceptance. In adopting this term, it should be employed in a definite sense to express the translucent, viscid, or slimy material, dimly granular under the lower powers, minutely fibrillated under the highest powers of the microscope, which moves by contracting and expanding, and which possesses a highly complex chemical constitution. The term ought not to embrace either the cell wall of the vegetable or animal cell, or the intercellular substance of the animal tissues. For although these have in all probability been originally derived from the protoplasm, by a chemical and morphological differentiation of its substance, or as a secretion from it, they have assumed formal and special characters and have acquired distinct functions. Protoplasm, as above defined, is a living structure endowed with great functional activity. It possesses a power of assimilation, and can extract from the appropriate pabulum the material that is necessary for nutrition, secretion, and growth. Growth takes place not by mere accretion of particles on the surface, but by an interstitial appropriation of new matter within its most minute organized particles. In cases, also, where the media in which the cell lives are suitable, as in the freely moving Amœba, or the white blood corpuscles, portions of the protoplasm may separate by budding from the general mass of the cell, and assume an independent existence; but the conditions under which the budding off of protoplasm can take place are exceptional in the higher organisms. Protoplasm, therefore, according to this definition, in addition to being a moving contractile substance, is the nutritive and secreting structural element of the tissues, and is always found relatively abundant where growth and the nutritive processes are most active.

In the fertilized ovum, after the process of segmentation has begun, and in the earlier stages of development of the embryo, the cells are nucleated masses of protoplasm, without cell-walls, and with no intercellular material. In the course of time, in animals more especially, an intercellular substance arises apparently by a

[1] Dr. J. M. Macfarlane has described as constantly present within the nucleolus of vegetable cells a minute body, which he terms *nucleolo-nucleus* or *endonucleolus*. He considers it, as well as the nucleolus, to become constricted and divided before the nucleus and the cell pass from the resting into the active phase of cell multiplication. See Trans. Bot. Soc. Edin., 1880, vol. xiv., and Trans. Roy. Soc. Edin., 1881–82, vol. xxx.

[1] "Lectures on the Physiology of Plants," by Julius von Sachs; translated by H. Marshall Ward, Oxford, 1887.

[2] The opinion for long entertained that the simpler algæ and fungi and cryptogams generally are destitute of nuclei has been shown by Schmidt and others to be incorrect.

differentiation of, or secretion from, the protoplasm. In many of the tissues this substance acquires such characters, magnitude, and importance as to overshadow the nucleated masses of protoplasm which it lies between and surrounds. The intercellular substance is the principal representative of the "formed material" of Dr. Beale. I cannot, however, agree with him in regarding it as passive and non-living or dead; for morphological and functional changes take place in it long after its original formation. Thus the hyaline matrix, or intercellular substance, of the young costal cartilages becomes converted into a fibrous matrix in the later period of life, and the striated substance of muscular fibre is one of the most physiologically active tissues in the animal body. In the general economy of the tissues, in the fitting of each to discharge the function for which it is specially intended, the intercellular substance plays an essential part. It gives strength to the bones, toughness and elasticity to ligaments and cartilage, motor power to muscles. It wastes by use and needs repair. But it is probably to the nucleated protoplasm within its substance that we are to look for the structural element which attracts to it the pabulum required for its nutrition, so that the interstitial waste which is consequent on its use may be made good.

The nucleus is also an active constituent of the cell, and in young cells is proportionately larger than when the cell is matured. It is doubtful if it plays a special part as a centre of attraction in secretion, or in the nutrition of the cell generally, an office which is most probably discharged by the protoplasm; but it undoubtedly acts as a centre for its own nutrition. Numerous observations, moreover, clearly prove the truth of the generalization originally propounded by Martin Barry, and confirmed by Goodsir, that the nucleus is intimately associated with the production of young cells. The karyokinetic phenomena which have been observed during the last fifteen years have established this on a firm basis, beginning with the segmentation of the yelk and nucleus within the fecundated ovum down to the latest period of cell formation.

But, along with the karyokinetic changes within the nucleus and its cleavage, there is also a cleavage of the protoplasm of the cell, so that the daughter cell consists of portions of both the nucleus and the protoplasm of the mother cell. The question therefore has been put whether the division of the protoplasm is a consequence or a coincidence of the division of the nucleus. I am inclined to think that the cleavage of the cell protoplasm is consequent on the nuclear changes; for it must be kept in mind that certain of the movements in and rearrangement of the chromatin fibres of the nucleus precede any rearrangement of particles in the cell protoplasm so far as yet observed, and, still more, the process of cleavage. Applying, therefore, to the cell the well-known economic principle of division of labour, and that differentiation of structure carries with it differentiation of function, I regard the protoplasm as the nutritive and secreting element of the cell, and the nucleus as its primary reproductive factor.

The present position of the cell theory differs therefore in many important respects from the doctrine advocated by Schwann and his immediate successors. Cells are no longer regarded as of necessity bladders or vesicles. A cell wall is not constant but of secondary formation. A free formation of cells within an extracellular blastema by deposition around a nucleolus to form a nucleus, and then around the nucleus to form a cell, does not take place. Young cells arise from a parent cell by division of the nucleus, followed by cleavage of the cell protoplasm, so that each cell is directly descended from a pre-existing cell. Although in so many of its details, therefore, the theory of Schwann has been departed from, yet the great generalization of the cellular structure of plants and animals holds good, and his work will continue to mark an epoch in the progress of biological science.

The study of the very remarkable series of karyokinetic phenomena above described has given an impulse to speculation and thought in connection with some of the most abstruse problems of life and organization. The question of the hereditary transmission of properties, both as regards the constituent tissues of the organism and the individual as a whole, has been put on a more definite physical basis. The penetration of the ovum by the spermatozoon, originally seen by Martin Barry in the rabbit, and extended to other animals some years afterwards by Newport, Bischoff, and Meissner, has been completed by the recent researches of Bütschli, Auerbach, Fol, Hertwig, and E. van Beneden. The conjugation or incorporation of the male pronucleus or head of the spermatozoon with the female pronucleus derived from the germinal vesicle, and the consequent formation of the segmentation nucleus, has been demonstrated. The segmentation nucleus is built up of chromatin fibres and nucleoplasm, derived from both the nucleus of the male sperm cell or the spermatozoon and the nucleus of the female germ cell. It is therefore a composite or hermaphrodite nucleus, and represents both parents. The cells derived from the segmentation nucleus in the early stage of segmentation contain chromatin nuclear particles, which are in direct descent from the chromatin fibres of the segmentation nucleus, and through it from the corresponding fibres of both the sperm and germ cells. From Nussbaum's and E. van Beneden's observations it would seem that each nucleus of the first pair of segmentation cells contains one-half of the chromatin threads of the male, and one-half of those of the female pronucleus. It is possible that an equal division of the male and female components of the nuclei takes place in every subsequent nuclear division, in which case the nucleus of every cell would be hermaphrodite or composite—that is, would represent both parents. The segmentation cells arrange themselves to form the blastoderm, which, in the more complex organisms, by the continuous subdivision of the cells, forms three layers; from which, by a prolonged process of cell division and differentiation, all the tissues and organs of the adult body are ultimately derived. Karyokinetic changes mark the process of cell division throughout, and each daughter cell receives from the mother cell chromatin nuclear material derived from both parents, which, without doubt, conveys properties as well as structure.

In the division of the segmentation nucleus within the ovum a cleavage of the protoplasm of the egg also takes place, and each daughter nucleus is enveloped by the protoplasm of the maternal egg. If during the period of nuclear division there is no interchange of matter between the nucleus and the protoplasm which incloses it, the cell protoplasm would then be derived solely from the ovum, and would represent maternal characters only, whilst the nucleus would possess characters derived from both parents. But if, as is most likely, during the process of karyokinesis, when the nuclear membrane has disappeared, an interchange of matter takes place between the nuclear substance and the cell protoplasm, the latter would then become, if I may say so, inoculated with some at least of the nuclear substance, and be no longer exclusively of maternal origin. Again, it should be stated that, as E. van Beneden has described, when the spermatozoon enters the egg it takes with it a portion of the protoplasm of the sperm cell. This apparently blends with the protoplasm of the egg itself. With Waldeyer, therefore, I would ask the question, Is this altogether without significance? It would seem, therefore, as if the whole of the cells of the body and the tissues derived from them are, as regards both nucleus and cell protoplasm, descended from material originally belonging to both parents.

Although ova in different organisms differ materially from each other in size, shape, the relative amount of food yolk which they contain, the mode of segmentation, and the presence or absence of a segmentation cavity, they all agree in this that the primordial cells of the egg are nucleated masses of protoplasm. Notwithstanding the general resemblance of the morphological units which thus mark the first stage in the production of young organisms, each fertilized ovum gives rise to an organism resembling that in which the egg itself arose. Hence the offspring resemble the parents, and the species is perpetuated by hereditary transmission, so long as individuals remain to keep up the reproductive process. During sexual reproduction the substance of the segmentation nucleus undergoes karyokinetic changes during the act of segmentation, and the question arises if the process of karyokinesis is the same for all organisms, whether plants or animals, or if there are specific differences. As the fertilized ovum is potentially the organism which is to arise from it, specific differences not unlikely exist in the minute structure of the segmentation nucleus, which may perhaps be expressed by modifications in the arrangement of the chromatin fibres and in the number of their loops. The varieties which have been described in the forms of the karyokinetic figures and polar radiations in different plants and animals may perhaps mark these specific differences.

But there is another question which merits consideration. Are the karyokinetic phenomena which show themselves in the cells of a given tissue characteristic of that tissue? and, if so, would it be possible to distinguish one tissue from another in the same organism by differences in the process of cell division? On this point a commencement seems to have been made towards obtaining some positive knowledge. Strasburger and Heuser think that they have obtained evidence in certain plant cells that such is the case; Rabl concludes, from observations on the epidermic cells of salamander, that the loops of chromatin fibres are constantly twenty-four in number in the same kind of cell in the same species of animal.

But in considering the different kinds of tissue, and the possibility of each kind possessing its characteristic karyokinetic process, it has to be kept in mind that more than one kind of tissue, each of which has its characteristic structure and function, arises from each layer of the blastoderm, so that there is a stage in development —a stage of indifferentism, if I may use the expression —when the blastoderm represents several tissues which have not yet differentiated. From the epiblast, for example, tissues so diverse in structure and function as cuticle and nerve tissue arise. Now, if there be a special karyokinetic process for the epidermal cells, and another for the nerve cells, does either of these correspond with the process of nuclear division in the cells of the epiblast in their stage of indifferentism, or do they both differ from it? When does the impulse reach the layers of the blastoderm, so as to produce in their constituent cells changes which so alter the characters of the cells as to lead to a differentiation into various forms of tissues, and to what is that impulse due? In the development of each species there seems to be a definite time within certain limits when the differentiation shall begin, and when the process of development of the tissues and organs shall be completed. This is an hereditary property, and is transmitted from parents to offspring. Is the impulse derived from the nucleus or from the cell protoplasm, or do both participate? As already stated, the nucleus is the element which is immediately descended from both parents, and which may therefore be supposed to be the primary morphological unit through which hereditary qualities are transmitted. But, as is most probable, the nucleus reacts on the cell protoplasm—on the element of the cell through which the ordinary nutritive functions are discharged. As a consequence of this reaction, when the appropriate time arrives in the development of each species for the commencement of the differentiation of the protoplasm of a cell, or group of cells, into a particular kind of tissue, the necessary morphological, chemical, and physiological changes take place. When once the differentiation has been effected, it is continued in the same tissue throughout the life of the organism, unless, through some disturbance in nutrition, the tissue atrophies or degenerates. Every multicellular organism, in which definite tissues and organs are to arise in the course of development, has therefore a period, varying in its duration in different species, in which certain of the properties of the cells are as it were dormant. But, under the influence of the potent factor of heredity, they are ready to assume activity as soon as the proper time arrives. When the process of differentiation and development is at an end, the organism has attained both its complete individuality as regards other organisms, and its specific characters.

Every organism, therefore, has to be viewed from both these points of view. Its specific position is determined by that of its parents, and is due to the hereditary transmission of specific characters through the segmentation nucleus. Its individuality is that which is characteristic of itself, and arises from the fact that in the course of development a measure of variability within the limits of a common species, from the organic form exhibited by its parents and by their other offspring, is permitted. In all likelihood the variability, as Weismann suggested,[1] is, to a large extent, occasioned by the bisexual mode of origin of so many organisms. By the expulsion of the polar bodies, during the maturation of the egg, portions of the ancestral germ plasm may be removed, and as corresponding molecules need not be expelled from each ovum, similar ancestral plasms would not be retained in each case, so that diversities would arise. There is also a possibility of the molecular particles of the segmentation nucleus and of the nuclei of the cells descended from it, having a method of arrangement and adjustment, and a molecular constitution characteristic of the individual as well as of the species. On this matter we have, however, no information. It is as yet a mere hypothesis. When we consider the extreme minuteness of the objects referred to, and recollect that it is only about fifteen years since karyokinetic phenomena were first recognized, it is astonishing what progress in knowledge has been made within this limited period. We owe this great advance to the much more complete magnifying and defining power of our microscopes, to the improved method of preparation of the objects, and to the acute vision and clear-thinking brains of those observers who have worked at the subject. By continuing the work, and extending it over a wider area, we may hope in time to be able to solve many questions to which we cannot now give an answer.

The nuclear material which makes up the substance of the male and female pronuclei, by the fusion of which the segmentation nucleus is formed, has been termed by Prof. Weismann the *germ plasm*. In a series of elaborate papers he has developed a theory of heredity,[2] based upon the supposed continuity of the germ plasm. He believes that in each individual produced by sexual generation a portion of the germ plasm derived from both parents is not employed in the construction of the cells and tissues of the soma, or personal structure of that individual, but is set aside unchanged for the formation of the germ cells of the succeeding generation—that is, for reproduction and the perpetuation of the species.

[1] See his essays, "The Significance of Sexual Reproduction in the Theory of Natural Selection," and "On the Number of Polar Bodies and their Significance in Heredity," translated in "Essays on Heredity" (Oxford, 1889).

[2] Translations of these papers have been published by the Clarendon Press, Oxford, 1889.

According to this theory, the germ plasm, more especially through the chromatin fibres, is the conveyer of hereditary structure and properties from generation to generation. Further, he holds that the cells, tissues, and organs, which make up the somatic or personal structure of the individual, exercise no modifying influence on the germ or reproductive cells situated in the body of that individual, which cells are also, he thinks, unaffected by the conditions, habits, and mode of life. In its fundamental idea Weismann's theory is in harmony with one propounded a few years earlier by Mr. Francis Galton (Proc. Roy. Soc. London, 1872; and Journ. Anthrop. Inst., vol. v., 1876).

In an address delivered at Newcastle in September last to the Anthropological Section of the British Association (NATURE, September 26, 1889), I reviewed this theory of heredity, and, whilst finding in it much with which one could coincide, I directed attention to points to which, I thought, objection might be taken. More especially I took exception to the idea that the germ plasm was so isolated from the cells of the body generally as to be uninfluenced by them, and to be unaffected by its surroundings.

On this occasion I propose to say a few words on the bearing of this theory on the development of the tissues and organs of the individual. If we examine the development of the embryo, say of one of the Vertebrata, we find that it makes a certain advance, varying in its time and extent according to the species, without any differentiation of a reproductive organ with its contained germ plasm being discoverable. I shall not enter into the much-disputed question of the layer or layers of the blastoderm from which the reproductive cells take their rise. But I may say that in the chick, both in the third and fourth day of incubation, a layer of germinal epithelium may be seen in close relation to the Wolffian duct and the pleuro-peritoneal cavity. At the end of the fourth day or in the fifth day this epithelium becomes thickened, and the primordial ova appear in it as distinctly differentiated cells. In the rabbit a corresponding differentiation does not appear to take place before the twelfth or thirteenth day. Up to the period of differentiation of the primordial ova, no isolation or separation of the reproductive cells and germ plasm has taken place; and, so far as observation teaches, there is nothing to enable one to say which cells of the blastoderm may give rise to primordial ova, or which may differentiate into cells for other histogenetic purposes. But before the germ cells appear, the rudiments of the nervous, vascular, skeletal, muscular, tegumentary, and alimentary systems, and the Wolffian bodies or primordial kidneys have all been mapped out. Up to this time, therefore, in all probability, a more or less complete diffusion of the germ plasm throughout either one or more of the layers of the blastoderm has taken place. The hereditary influence conveyed by the germ plasm would thus be brought to bear upon the cells of the blastoderm generally, so as to impart to them the power of undergoing at the appropriate period the morphological and chemical differentiation to form the several tissues. As the tissues and organs are derived through division of the nuclei from the cells of the blastoderm, the continuity of the hereditary influence exercised over them is kept up, even after the germ plasm has become isolated, and the entire organism is moulded so that it acquires its specific and individual characters.[1]

But the diffusion of the germ plasm throughout either the whole of the blastoderm, or a part thereof, of necessity so intimately associates it with the formative cells of the tissues generally, that it is difficult, if not impossible, to comprehend how in its turn it can be unaffected by them. Before, therefore, it again becomes stored up or isolated in an individual, in the form of ova or sperm cells, it has in its stage of diffusion been brought under precisely the same influences as those which in the embryo affect the formative cells of the whole body.

From the observations and reasoning of Wilhelm His (Proc. Roy. Soc. Edin., April 2, 1888), there can, I think, be no question that the layers of the blastoderm are affected by pressures and other mechanical conditions. These pressures would produce or modify flexures, or occasion a diminution in dimensions in some directions and an increase in others; and in this way would tend to affect either the form of the entire organism, or the form and relations of its constituent parts, or perhaps both. Should such modifying influences come into operation either before the isolation of the germ plasm, or when it was in a plastic or impressionable condition, one could conceive that it might be affected by them. Molecular changes might thus be induced in the germ plasm of such a kind as to modify the properties of the chromatin constituent of the nuclei, so as to induce in it and the germ plasms descended from it corresponding modifications, which would become hereditary. If such an hypothesis be granted, it would follow that the external conditions would exercise a perceptible influence on the germ plasm of the reproductive cells, both in the individual in which they first manifested their effect and in the generations which are descended from him.

If the germ plasm, from the first stage of development of each organism, were completely isolated from the cells from which all the other cells of the body were produced, it would be possible to conceive its transmission from generation to generation unaffected by its surroundings. But as in each individual a stage of diffusion or non-isolation precedes that of differentiation into the special reproductive apparatus, it follows that the conditions which would secure the germ plasm and the soma cells from mutual interaction are not complied with. On this ground, therefore, as well as for the reasons previously advanced in my Newcastle address on heredity, I am unable to accept the proposition that there can be no transmission to the offspring, through the reaction of the soma on the germ plasm, of characters which may be acquired under direct external influences. But in questioning the accuracy of the proposition that somatogenic "acquired characters" are incapable of being transmitted, I do not of course contend that all the characters which may be acquired during the lifetime of an individual are perpetuated in his descendants.

THE LABORATORY OF VEGETABLE BIOLOGY AT FONTAINEBLEAU.

THIS Laboratory, the establishment of which we have already announced, has now been in full working order, as far as the present buildings will permit, since May 15. We are enabled to furnish our readers with the following account of its scope and design, with the accompanying sketches, from an article supplied by M. Jumelle to the *Révue Générale de Botanique*.

The Laboratory was established at the suggestion of M. Liard, the Director of Higher Instruction in France, and

[1] On the question of the influence exercised by the germ plasm on the tissues, I may refer to some most suggestive remarks by Sir James Paget, published forty years ago, in the *London Medical Gazette*, 1849, in one of his lectures (VI.) on "The Processes of Repair and Reproduction after Injuries:"—"In every impregnated germ we must admit that properties are implanted which, in favourable conditions, issue in the power to form, of the germ and the materials it appropriates, a being like those from which it sprang. And, mysterious as it may seem, yet must we conclude that a measure of those properties is communicated to all the organic materials that come within the influence of the germ; so that they, being previously indifferent, form themselves in accordance with the same specific law as that to which the original materials of the germ are subject. So through every period of life the same properties transmitted and diffused through the whole organism are manifested in the determination of its growth and maintenance in its natural degeneration, and its repair of every part, in accordance with that type or law which has prevailed in every individual of the species." See also a lecture "On the Formative Process," in "Lectures on Surgical Pathology," vol. i., London, 1853.

is regarded as an *annexe* of the Botanical Laboratory of the Faculty of Sciences at the Sorbonne, being under the direction of M. Gaston Bonnier, the Professor of Botany at the Sorbonne. Its foundation was due to a consideration of the difficulties which necessarily attach to culture-experiments and physiological researches when carried on in large towns. For these purposes an advantageous locality presented itself in Fontainebleau, with the rich herbaceous and arborescent flora of the neighbouring forest, an abundant supply of water, and ready access to Paris. A portion of the forest (see Fig. 1) is inclosed within the territory attached to the Laboratory.

It is intended in the future to make important additions to the building at present constructed. The room for experimental researches is represented by S in Fig. 2; it will accommodate 24 workers. Those who are engaged in microscopical researches, or the study of the lower forms of vegetable life, work in galleries placed at about one-half the height of the room; the floor is intended for physiological experiments, which, with the necessary apparatus, require a larger space. Here are placed the instruments required for the study of vegetable chemistry—furnaces, balances for delicate work, glycerin-troughs, apparatus for sterilization, &c.; others will be added as needed. Opening out of this hall (B and P, Fig. 2) are the director's room and the library. Other rooms (A, A, Figs. 2 and 3) are occupied by M. Duval, the director of cultures; and on the upper story are chambers for some of the students. In the grounds attached are frames (C, Fig. 1), and a greenhouse (S)

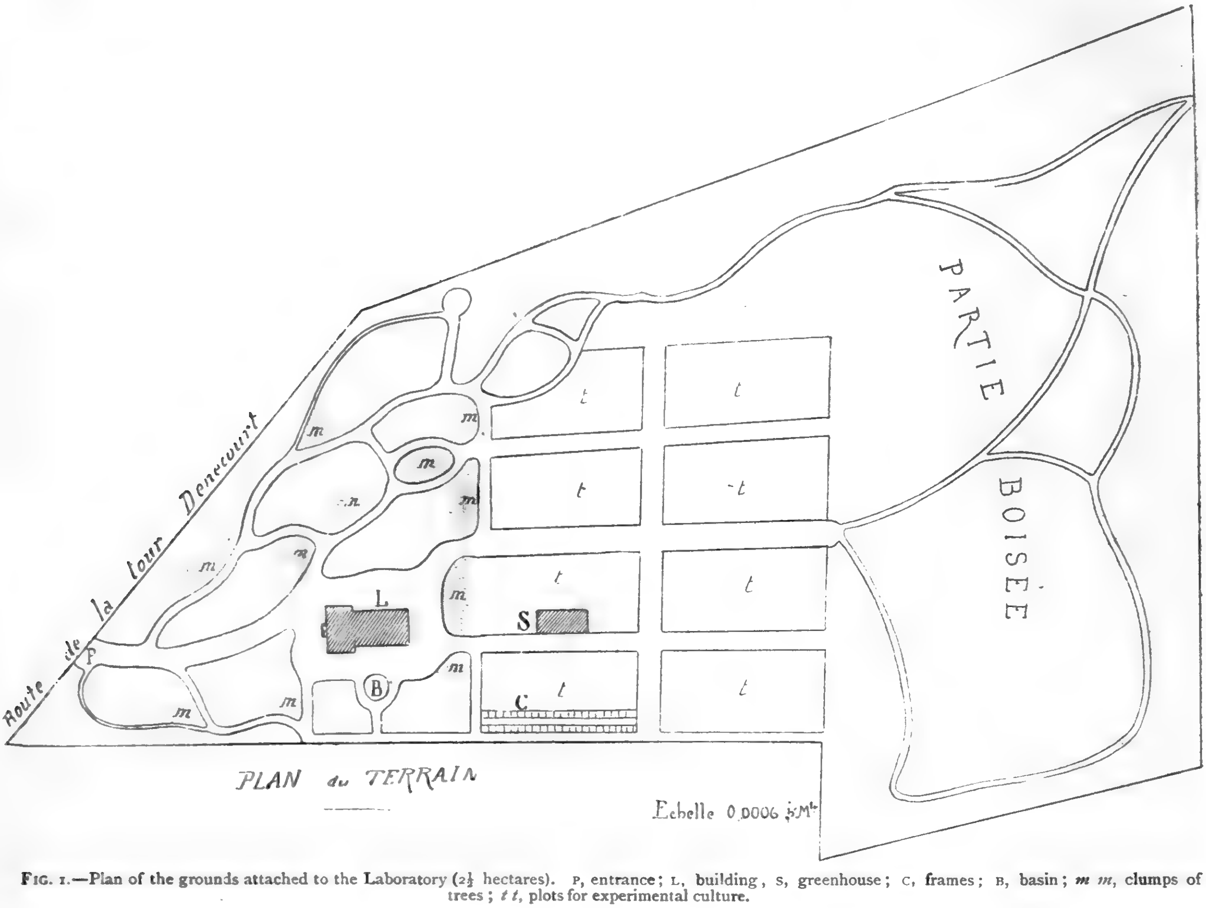

Fig. 1.—Plan of the grounds attached to the Laboratory (2½ hectares). P, entrance; L, building, S, greenhouse; C, frames; B, basin; *m m*, clumps of trees; *t t*, plots for experimental culture.

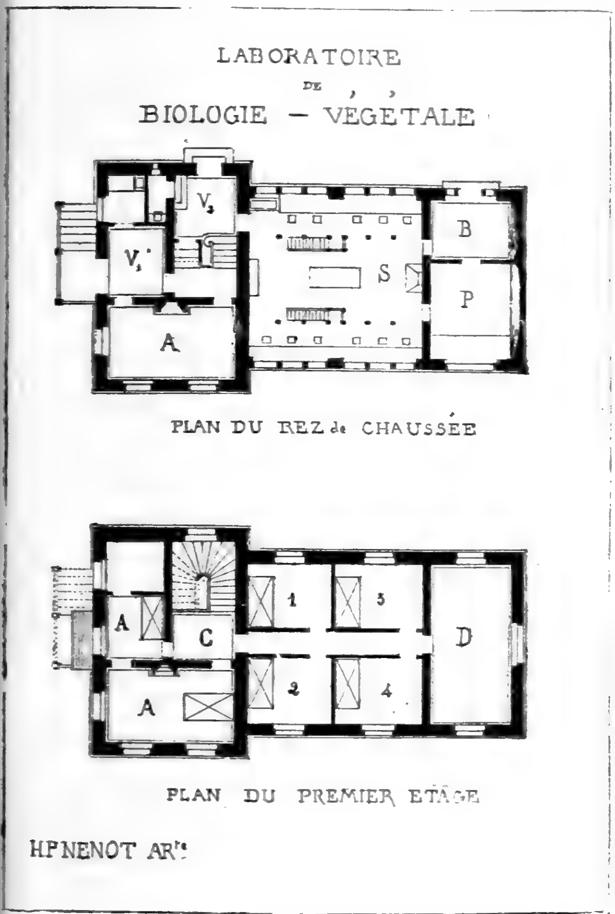
divided into a hot and cold portion; in the latter is placed apparatus necessary for physiological experiments.

One object aimed at by the establishment of the Laboratory is to provide facilities, already afforded in the case of animals in zoological laboratories, for the study of plants in the localities and under the conditions in which they are found in Nature. Hitherto, experiments in vegetable physiology have been mainly carried out on specimens which have been transplanted for the purpose, and which are therefore subjected to unfavourable or unnatural conditions of light, air, soil, &c., which may materially invalidate the results. This objection applies largely to experiments carried on in botanic gardens. To meet this difficulty, a portion of the actual forest (see Fig. 1) has been inclosed within the precincts of the Laboratory; and numerous plots (*t*, *t*) are also set apart for experimental cultures. In the former are a number of trees and herbaceous plants growing in their natural habitat in all stages of development. It is hoped that in this way much light will be thrown on the diseases, whether due to the attacks of parasites or to unfavourable vital conditions, to which plants are subject. It is intended that the culture-plots shall not be devoted exclusively to the use of students in the Laboratory, but that other experiments shall be carried on by M. Duval at the desire of, and under the conditions prescribed by, outside workers. The study of vegetable pathology, and especially of the diseases which attack vines and forest-trees, is one of the special objects for which the Laboratory has been established; and, to aid in these researches, relations have already been opened with horticulturists and viticulturists, and with the Administration of Forests; and the occupiers of neighbouring estates have placed their resources at the disposal of the director.

In addition to the Laboratory at Fontainebleau, a new one is also being built at the Sorbonne itself, with a large lecture-room, galleries for collections, a library, a greenhouse, a photographic room, and twelve workrooms.



FIGS. 2, 3.—Ground floor: V V, vestibules; S, hall for research; P, Director's laboratory; B, library. First floor: C, landing: D, 1, 2, 3, 4, chambers for students; A A, rooms of the director of cultures.

The Director of the Laboratory at Fontainebleau offers a cordial invitation to foreign botanists who may desire to avail themselves of the facilities for work afforded by it.

BENJAMIN FRANKLIN.

THE Official Report, issued by the American Philosophical Society, of the celebration of the centennial anniversary of the death of Benjamin Franklin, April 17, 1890, has just been sent to us. The Society, in January last, held a stated meeting, at which it was resolved to form a Committee of five members, to be appointed by the President, who should be empowered to take all necessary action. The following was the form of the resolution that was drawn up by the Committee:—"That we commemorate in a becoming way the approaching centennial anniversary of the death of Benjamin Franklin, and that a series of short addresses upon his life, character, and work be delivered before the Society upon this occasion."

The Society is to be congratulated on the success with which the idea was carried out. It is right that the world, on fitting occasions, should be reminded of the achievements of so great an investigator. Franklin had all the qualities of mind which are necessary for the extension of knowledge by means of observation and experiment, and his career marked one of the most important stages in the development of science. Englishmen regard his work with hardly less pride than Americans, and the memory of what he accomplished must always be one of the links that serve to unite the two peoples.

In the evening of the anniversary day, members and their guests assembled at the Association Hall in the city of Philadelphia. Mr. Talcott Williams began the proceedings with a few remarks on the occasion of the gathering. He then informed the audience that the Society had summoned the biographer of Franklin; it had called upon the historian of the land in which he served his country, upon the man of science, upon one who was both the man of science and of letters, and lastly upon the President of the Society, to represent the civic and associated activities in which Franklin was engaged.

In the following notes we shall give brief extracts from some of the speeches that were delivered. Franklin, the youngest son of a family of seventeen, began his career at Boston. He wished to go to sea, but his mother thought it would be better for him to become a minister. His father, having tried hard to make him a tradesman, bound him over to an elder brother to learn printing. The apprenticeship did not last long, as the brothers disagreed, and what with insults, quarrels, and blows, they parted—"the one to drag out a humble existence, the other to become the most illustrious American of his day." Travelling about looking for work, Franklin came across William Keith, who sent him to Boston, and then to London. On reaching the latter place he found out that "Keith was a knave, and himself a dupe." During his stay in London he wasted his substance, misused money, and kept bad company; but after some time he made the acquaintance of a merchant, who gave him a situation. Going back to Philadelphia with him, he commenced to "keep books, sell goods, and learn the secrets of mercantile affairs." Owing to the death of the merchant, Franklin was once more at large, and this time, with the help of a friend, he set up a "new printing office in High Street near the market."

From that hour he prospered, bought out his partner, married, founded one of the best newspapers, published the famous almanac, and was made Postmaster-General. Having now become wealthy by a strict adherence to the maxims of "Poor Richard," he sold his shop, newspaper, &c., and gave his time to the study of science. Before he had reached the age of fifty he had won for himself the Copley Medal, and membership of the Royal Society.

He now dropped scientific studies and returned to politics, and was loaded with public duties. Among other things he was appointed Postmaster-General of the Colonies, sent by the Assembly with its Speaker to hold a conference with the Indians at Carlisle, and then to the Albany Conference, where he presented his famous plan of union. On his return to Philadelphia in 1761, his intention was to settle down again and study, but he was again drawn into politics by the conspiracy of Pontiac, and the massacre of the Conestoga Indians by the men of Donegal and Paxtang.

After this he wrote many articles on American affairs for the English newspapers, and it was about this time that he republished a London edition of the "Famous Letters," and brought out "The Votes and Proceedings of the Freeholders and other Inhabitants of

Boston"; he also sent over the "Hutchinson Letters," and underwent the memorial examination before the Privy Council.

Having been abroad ten years and six months, he turned his face homewards, and found that great changes had taken place; the city had grown considerably, and the people were more prosperous. The greatest change seems to have occurred in his family; his wife was dead, his daughter married, and his son estranged in politics. Luckily, Franklin was soon absorbed again in public affairs, so that he had no time to consider his misfortunes.

The day after he landed, he "was chosen a member of the Continental Congress, took his seat four days later, and served for 14 months; was on eleven committees, was made Postmaster-General; was sent on one mission to Washington at Cambridge, and on another to Arnold at Quebec; was despatched after the disastrous battle of Long Island, to confer with Lord Howe; and in September 1776, was sent out to join Arthur Lee and Silas Diane in France."

There he was received with great enthusiasm, and "became the sensation of the hour." He concluded the treaty of alliance with France, the treaty of amity and commerce, negotiated loans for great sums of money, and in 1783 signed the treaty of peace with Great Britain.

In 1785, old and loaded with honours, he returned to Philadelphia. Here he was made a Member of Council, and the Council and Assembly made him President of the State, and while holding this office he was sent to the Convention that framed the Constitution of the United States. It was about this time that his fame was at its highest, and everyone honoured and looked up to "the venerable Dr. Franklin, our illustrious countryman and friend of man," "the father of American independence." The closing years of his life were passed among his friends and admirers, and he died on April 17, 1790.

The epitaph that was placed over his tomb was written by himself, and is quite worth repeating:—

"The body
of
BENJAMIN FRANKLIN,
Printer
(like the cover of an old book,
its contents torn out,
and stript of its lettering and gilding),
lies here food for worms.
Yet the work itself shall not be lost;
for it will, as he believed, appear once more
in a new
and more beautiful edition
corrected and amended
by
The Author."

Franklin was a voluminous writer, and wrote with expression. To use the words of Mr. Brown Goode, who spoke on "the literary labours of Benjamin Franklin," "he wrote habitually with a single eye to immediate practical results. He never posed for posterity. Of all the writings to which he mainly owes his present fame, it would be difficult to name one which he gave to the press himself or of which he saw the proof. Yet he never wrote a dull line, nor many which the century of time has robbed of their interest or value."

The literary remains of Franklin may be classified as follows:—

(1) "The Autobiography," from 1706–57.

(2) "Poor Richard's Almanac," in twenty-six annual issues, 1732–58, culminating in "Father Abraham's Speech at the Auction."

(3) Essays upon manners, morals, and the science of life, including the so-called "Bagatelles"; in all sixty titles or more.

(4) Tracts and papers upon political economy, finance, and the science of government; in all about forty titles.

(5) Essays and tracts, historical and political, concerning the American Revolution and the events which immediately preceded and followed, 1747–90.

(6) Scientific papers from 1737–90; in all 221 titles, and nearly 900 octavo pages.

(7) Correspondence, diplomatic, domestic, and literary, 1724–90; in all some twelve hundred letters, while many still remain unpublished.

Dr. J. W. Holland gave a very interesting account of the scientific labours of Franklin in the various branches of natural philosophy. Considered in their general character, they fall into a few groups, such as labour in sanitary science, in the art of navigation, in meteorology, and in electricity.

The science of electricity in Franklin's time was in its infancy. The only facts known about it were that some substances could be electrified, that the zigzag sparks which could be drawn from a rude machine resembled the lightning-flash, and that the Leyden jar enabled the experimenter to "imprison the fiery spirit and perform many remarkable tricks with it." Having reached middle age and just retired from business, he set to work with the frictional machine and the jar.

He first formed "a coterie for mutual suggestions and encouragement" with three of his friends who were very interested in these experiments; and between them they made a great advance, constructing their own machines, and making "new demonstrations of attraction and repulsion, and of the power of electricity to produce light, heat, mechanical violence, nervous shock, and even death." As a result of these and other experiments, he invented the lightning-conductor, which at that time was accounted "the most brilliant application of science that had been known," and projected his apt and simple theory of an electric fluid, explaining the cause of positive and negative action, which "held sway for so many years that to this day its nomenclature is retained in spite of defects revealed by recent advances in knowledge."

In concluding these brief extracts, we cannot do better than quote the words of one of the speakers:—

"Such men are few in any age; their number is not great in all the combined centuries that together make up the short life of our race upon this planet. It is only meet that we should cherish their names with respect, and gratefully hand down to posterity the story of their honourable and meritorious deeds."

NOTES ON THE HABITS OF SOME COMMON ENGLISH SPIDERS.

SOME years ago I sent to NATURE (vol. xxiii. p. 149) an account of the behaviour of the common small garden spider when a sounding tuning-fork is brought near. If the fork is made to touch any part of the web, or the twigs or leaves by which the web is supported, the trembling of the web completely deceives the spider, so that, after rapidly finding which radial line is most disturbed, she runs along this one and attempts to secure the tuning-fork. She fails to discover in the cold and polished steel anything different from her usual food; or rather, being led by instinct to eat that which buzzes, she struggles in vain to find a soft place in the armour of her prey.

On the other hand, if the tuning-fork is brought near one of these little spiders while she is waiting in the centre of her web, she generally drops instantly, but will climb up again as quickly as possible if the vibrating fork is made to touch the web.

More recently Mr. and Mrs. Peckham, who have made an elaborate study of the mental powers of spiders (*Journal of Morphology*, vol. i. p. 383), have repeated these experiments, and have confirmed them in every essential particular.

They found that many geometrical spiders would drop when a vibrating tuning-fork was brought near them, but that after much teasing in this way they would sometimes learn to take no notice. They conclude that this dropping habit is of direct service to them, in enabling them to escape from birds or wasps which prey upon them.

While staying recently with Mr. Romanes, in Ross-shire, I made some observations in this connection which are possibly worth recording.

The small geometrical spiders which abounded on the gorse bushes near the sea behaved as described above, while, as I have noticed many times before, the diadema spiders, which also were abundant, were affected in a totally different manner. If the tuning-fork is held near them, they throw up their four front legs, either perpendicularly or even further back, and as soon as the fork is within reach strike at it so violently that the blow may be plainly heard. A buzzing insect carried near is caught by the diadema spider in this way, and speedily wound up.

There were a number also of small brown geometrical spiders, which I believe were young diademas; these dropped when a sounding tuning-fork was brought near them even more readily than the full-grown little spiders.

Instead of bringing a tuning-fork near the spiders, I made a sudden and high-pitched shout, taking care that my breath should not complicate the situtation. The effect, when a great number of spiders were resting on their webs near together, was sufficiently striking. The diademas threw up their legs simultaneously, and struck in the air at the imaginary insect, while the full-grown little spiders, and what I believed to be the young diademas, all dropped out of their webs into the branches below.

The suggestion of Mr. and Mrs. Peckham, that this habit is a protection against wasps, is made the more probable by the difference in the behaviour of the full-grown diadema, which would certainly not be afraid of a wasp, and the little spiders. However, the tactics of a wasp that I watched left no doubt in my mind that this explanation is correct. The wasp, when I first saw it on a gorse spray, was evidently intent on something. It ran up the spray until it came to the silken tube in which the little spider dwells when not on the web. The spider retreated further into the tube, while the wasp was struggling among the spines and the silk to dislodge her. After a short time the wasp gave up the attempt, and flew away for a few yards. It then very suddenly darted at another spider, seized her before she had time to drop, and carried her off to a branch close by. This was done so quickly that I could not follow the details of the attack; but it is certain that the wasp, which did not carry a spider a moment before, had without alighting taken the spider off her web. It would appear that the dropping habit of the spider has reacted on the wasp, and has developed in it a speed of attack sufficient to counteract the spider's only means of escape.

I have not found that the little spider is less attracted by low notes than by high; a variety of forks, forceps from a box of chemical weights, or a carpenter's square banged on the knee, all seem to deceive her equally well, but a vibration of great amplitude causes her to retreat to a place of safety. The spider seems to judge of the necessity for prudence by the violence of the insect rather than by the natural note of its wings. She is terrified by a heated tuning-fork, which is not too hot to hold.

Mr. and Mrs. Peckham have formed a low estimate of the spider's intelligence as distinct from instinct. They found that a spider which has the habit of carrying its cocoon was quite satisfied with a lead shot slipped into the silk covering of the eggs, and laboriously carried about. The following are a few of many experiments which I have made, which lead to the same conclusion. A large diadema which had just caught and wound up a large fly, and had carried it up to its retreat, left it hanging by a short line while she proceeded, according to the usual habit of this kind of spider, to carefully clean herself before the meal. Meanwhile I managed to replace the fly by a piece of cork without disturbing the spider. When the toilet was complete, she pulled up the line from which the supposed fly was suspended, and tried to eat the cork. She was a long time trying every part of the cork before she finally let it drop. A piece of an india-rubber ring was twisted up until it had acquired a state (well known to school-boys) of spasmodic recoil. This was placed on the carpet-like web of a large black house-spider, which Mr. Pocock tells me is known to naturalists as *Tegenaria atrica*. These, like other house-spiders, appear to be far more wary than the geometrical sort. The india-rubber was made to move slightly by being pinched from below, and then the spider pounced upon it. I did not allow the spider to carry it off, but made it seem to struggle and resist by manipulation with a pair of forceps under the web. The spider became more and more desperate, and at last, when the web was much damaged by the battle, I dragged the rubber away; but the spider could not allow this, and clambering through the hole made in the web, and hanging by her fourth pair of legs, seized the escaping insect. I then let go, and the spider carried the piece of india-rubber away to her den, perfectly satisfied. However, she did not seem to appreciate her meal, for, after biting it on every side, she was obliged to take it to the edge of her web and drop it. I then picked it up, and was surprised to find the spider willing to be similarly deceived again.

These spiders will come to a tuning-fork once or twice perhaps, but the moment they touch it they fly terrified, as they do from a common bluebottle with mica on its wings. They seem generally thirsty, and will drink water placed upon the web, and if it is scattered in drops they are able to find the drops, but by what process I do not know. The diademas, too, especially when old, and only able to mend old webs, not to spin new ones, are always ready to drink. They will hold a piece of wheat straw six or eight inches long which has a drop of water upon it until they have drunk the water; but while the little spider is so insensitive in taste as not to entirely reject a fly that has been soaking in a parafin lamp, especially if it is made to buzz with a tuning-fork, the diadema has a strong objection to alcohol, even well diluted, and rubs her mouth against anything near by after tasting it, so as to get rid as quickly as possible of the noxious fluid. Is it possible that the numerous spiders which are found in secondary batteries have been killed by the acid when attempting to drink, or are they destroyed by accidentally meeting the acid in their ordinary descents? The *Tegenaria* is aware of the shout which causes the diadema to strike and the little spider to drop, but the effect is a jump such as is executed by anyone when suddenly startled.

It would appear that the only sense which is developed to any extent, and that most marvellously, is the sense of touch; hearing, taste, and smell to a small degree; but sight, as we understand the term, in spite of their numerous eyes, seems to be absent. The *Tegenaria* will stand within half an inch of a fly feigning death, without being able to find it; while the geometrical spiders, under like circumstances, gently pluck line by line until the effect of the inertia (not weight) of a motionless object guides them to the proper place.

These remarks do not apply to the hunting spiders.

C. V. BOYS.

NOTES.

The following is the list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1891, at the forthcoming anniversary meeting on December 1:—President: Sir William Thomson. Treasurer: Dr. John Evans. Secretaries: Prof. Michael Foster, the Lord Rayleigh. Foreign Secretary: Archibald Geikie. Other members of the Council: Prof. William Edward Ayrton, William Henry Mahoney Christie, Prof. W. Boyd Dawkins, James Whitbread Lee Glaisher, Dr. Hugo Müller, Prof. Alfred Newton, Sir William Roberts, William Chandler Roberts-Austen, Prof. Edward Albert Schäfer, Sir George Gabriel Stokes, Bart., Lieut.-General Richard Strachey, R.E., Prof. Joseph John Thomson, Prof. Thomas Edward Thorpe, Sir William Turner, Prof. Sydney Howard Vines, General James Thomas Walker, C.B.

The recent delimitation of the spheres of influence of Great Britain and Germany in Tropical Africa will probably give a considerable impulse to the systematic investigation of its flora by the travellers and botanists of either nation. An arrangement has, therefore, been made between Kew and the Royal Botanic Museum at Berlin, for the regular exchange of African collections. In accordance with it, the extensive herbarium of Marocco plants formed by the late John Ball, F.R.S., after the selection for Kew of all unique speci mens, is about to be transmitted to Be rlin.

The Geological Photographs Committee, appointed by the British Association to arrange for the collection, preservation, and systematic registration of photographs of geological interest in the United Kingdom, have issued a circular inviting the co-operation of geologists in their work. At the Leeds meeting of the British Association, the Committee exhibited, as the result of their first year's operations, a collection numbering upwards of 270 photographs, many of which illustrated geological sections, and other features of considerable scientific interest. The Committee, however, point out that, so far as the work has yet proceeded, only a small proportion of the counties in the British Islands have been represented; and they urge upon geologists the desirability of further assisting the scheme, with the object of forming a national collection of photographs illustrating the geology of our own country, which will ultis mately be deposited in some convenient centre. The Committee wish to receive copies of suitable photographs, which will be duly numbered and registered, or to be favoured with the following information, viz.:—(1) Lists and details of photographs of geological character already in existence. (2) Names of local societies, or persons, who may be willing to further the objects of the Committee in their own district. (3) Particulars of localities, sections, boulders, or other features which it may be desirable to have photographed. A circular of instructions has been drawn up, copies of which will be supplied to any persons who may desire to have them. The Secretary of the Committee is Mr. Osmund W. Jeffs, 12 Queen's Road, Rock Ferry, Cheshire.

The American Association for the Advancement of Science will hold its session for 1891 at Washington. Among the subjects on which papers and discussion are especially invited are: the absorption of gases and of fluids by, and the movements of water in plants, the aëration of aquatic plants, and transpiration.

The eighth Congress of the American Ornithologists' Union will meet at Washington on November 18. The meetings will be held at the U.S. National Museum.

The Society of Arts has issued its programme of "sessional arrangements." The following are the Cantor Lectures, which will be delivered on Monday evenings at eight o'clock: Prof. Vivian B. Lewes, "Gaseous Illuminants" (five lectures), November 24, December 1, 8, 15, 22; A. J. Hipkins, "The Construction and Capabilities of Musical Instruments" (three lectures), January 26, February 2, 9; Gisbert Kapp, "The Electric Transmission of Power" (three lectures), February 16, 23, March 2; Prof. R. Meldola, F.R.S., "Photographic Chemistry" (three lectures), March 9, 16, 23; Hugh Stannus, "The Decorative Treatment of Natural Foliage" (four lectures), April 13, 20, 27, May 4.

One lamentable result of the very rainy summer and autumn has been the partial submergence of the Botanic Garden at Prague, by which incalculable damage has been done to the very fine collection of plants under the care of Prof. Willkomm, the work of many years' careful and untiring labour. The fires in the hot-houses were extinguished, and one glass-house entirely destroyed. The unique collection of succulent plants, including 200 species of *Sempervivum* and 320 of *Cactus*, suffered irreparable injury. The splendid collection of models and preparations only recently made has been rendered almost valueless; in the lecture-room, where it was placed, the water stood at a height of about 5 feet 6 inches.

A quaint custom, dating back to Anglo-Saxon times, known as payment of "wrath silver," was recently observed at Knightlow Hill, a tumulus between Rugby and Coventry. It consists of tribute payable by certain parishes in Warwickshire to the Duke of Buccleuch. The silver has to be deposited at daybreak in a hollow stone by representatives of the parishes, the penalty for default being forfeiture of a white bull with a red nose and ears. The representatives afterwards dined together at the Duke's expense.

The Deutsche Seewarte and the Danish Meteorological Institute have just issued two more quarterly volumes of synchronous daily weather charts of the North Atlantic, bringing the series of this valuable publication down to November 1886. These volumes show very clearly the difference of conditions existing over that ocean between summer and autumn; the difference of atmospheric pressure is much less in summer, and consequently the winds are lighter. A cursory glance at the low-pressure areas shows their important effect upon the weather of their vicinity, and the history of the severe gale which visited this country on October 15–16, 1886 (a discussion of which appeared in the Quarterly Journal of the Royal Meteorological Society for January 1887), may be clearly traced on the charts, as well as several other disturbances which reached our coasts from the Atlantic. The importance of such work can hardly be over-estimated, but its value would be further enhanced if the publication could be made nearer to current date.

The year ending last April was remarkable in point of weather in St. Petersburg. Thus (as Dr. Woeikof points out) only once in 130 years was the mean temperature of the seven months October to April warmer than in this year—viz. in 1821–22, when the excess was 4°·2 C. (this year 3°·6). The normal order of the months was not disturbed, as so often occurs in warm winters. It looked as if St. Petersburg had moved into a warmer and more continental climate. In the number of warmest days of the 130 years series, October and April (1889–90) are unequalled. Reckoning as summer days those with 16° (the mean of summer) or over, it appears that between the last and the first summer day the number of days in 1889–90 is 24 less than the shortest period hitherto observed, two months shorter than the mean, and 112 days shorter than in 1821–22. And it is curious that the period in question is longest in the year in which October to April was warmest (1821–22), but shortest in the next warmest (1889–90).

The following details of the earthquake in Persia in June, last have been received from Dr. Jellisew, a Russian doctor who, on the evening of the 28th inst., was at a considerable distance from Teheran, on his way from Meshed to the capital. The centre of the earthquake seemed to be Tasch, a village on the side of a mountain, and close to a deep precipice. The noise of the shocks was so loud that Dr. Jellisew was awakened from his sleep, and in a few minutes several houses fell together. Others had great cracks in their walls. Many people rushed into the fields; most of those who remained in the houses were killed. Large blocks of rock are said to have burst asunder.

A STALACTITE cave has been discovered recently in one of the State forests near Bissingen, in Würtemberg. The entrance is said to be 15 metres high, and 3 or $3\frac{1}{2}$ wide.

PROF. J. MARK BALDWIN contributes to *Science*, October 23, a note of some interesting experiments relating to the "origin of right- or left-handedness." The subject of them was his own child, and they extended over the greater part of the first year. The following are the points recorded:—(1) He found no trace of preference for either hand as long as there were no violent muscular exertions made (based on 2187 systematic experiments in cases of free movement of hands near the body, *i.e.* right hand 585 cases, left hand 568 cases, a difference of 17 cases; both hands 1034 cases; the difference of 17 cases being too slight to have meaning). (2) Under the same conditions the tendency to use both hands together was about double the tendency to use either (seen from the number of cases of the use of both hands in the statistics given above), the period covered being from the child's sixth to her tenth month inclusive. (3) A distinct preference for the right hand in violent efforts in reaching became noticeable in the seventh and eighth months. Experiments during the eighth month on this cue gave, in 80 cases, right hand 74 cases, left hand 5 cases, both hands 1 case. In many cases the left hand followed slowly upon the lead of the right. Under the stimulus of bright colours, from 86 cases, 84 were right-hand cases, and 2 left-hand. Right-handedness had accordingly developed under pressure of muscular effort. (4) Up to this time the child had not learned to stand or to creep; hence the development of one hand more than the other is not due to differences in weight between the two longitudinal halves of the body. As she had not learned to speak, or to utter articulate sounds with much distinctness, we may say also that right- or left-handedness may develop while the motor speech-centre is not yet functioning.

AT a recent meeting of the Paris Société de Biologie, M. J. Kunckel d'Herculais announced that he had been able to trace the entire development of the parasitic *Mylabris schrebersi*, which, like the *Epicauta* studied by C. V. Riley, live parasitically on different *Acridia*, on *Stauronotus maroceanus* particularly.

WE learn, from the *Oesterreichische botanische Zeitschrift*, of interesting botanical results obtained from Herr J. Bornmüller's expedition to Asia Minor. From Amasia he had paid a five-weeks' visit to the mountain district of Siwas, Kaisarieth, and Jusgat, where he found, at altitudes varying from 1800 to 2500 metres, a flora differing widely from that of Amasia; many Alpine species with showy flowers, belonging to the genera *Primula*, *Gymnadenia*, *Papaver*, *Ranunculus*, *Globularia*, *Geranium*, *Centaurea*, *Bupleurum*, *Fritillaria*, &c., being found in great abundance. The ascent of the steep cone of Yildiz-dagh, 2520 metres, occupied 12 hours. Four days were required for the ascent of Mount Argæus, the higher elevations of which were covered with immense masses of snow. The mountain is 13,000 feet high, and for the last 1500 metres nothing but snow and glacier was traversed; the actual summit of 150 feet was found inaccessible. At a height of 2900 metres all traces of trees had disappeared, and the only shrubs found were starved specimens of *Juniperus nana* and tragacanth in the fissures of the rocks; but the pastures were covered with an abundant and brilliant vegetation. In the snow-covered regions the night-temperature was $+ 2°-3°$ R. Several new species were collected, among them a beautiful orange-yellow *Fritillaria*. On his return to Amasia he found the herbaceous vegetation almost entirely scorched up by the heat of the sun. Herr Bornmüller was then starting for the sources of the Gök-Irmak in Paphlagonia, whence he hoped to bring rich collections, the only botanist who has hitherto visited that district being Wiedemann, in 1840; and his collections are to be found only in the herbarium at St. Petersburg.

WITH reference to our Notes on scientific guide-books to Switzerland, a correspondent sends us the following list:—(1) "Scientific Guide to Switzerland," by J. R. Morell, H.M. Inspector of Schools (Smith, Elder, and Co., London, 1867), 396 pages and index (same size as International Scientific Series). It treats of orography, geology, hydrography, meteorology, glaciers, fauna and flora of Switzerland. (2) "Le Monde des Alpes," a picturesque description of the Alps, and particularly of the animals which inhabit them, translated by O. Bauritt from the German of Dr. F. von Tschudi, "Das Thierleben der Alpenwelt," published by H. Georg, at Geneva and Bâle, 864 pages (same size as Prestwich's "Geology"), and 24 full page woodcuts, tinted, published in 1870, from the second German edition. (3) "Les Alpes," par H. A. Berlepsch (same size as Prestwich's "Geology"), with 16 tinted full plate cuts, published by H. Georg, at Geneva, 1870. The original is in German, with 441 pages. It contains an excellent description of the natural phenomena of Switzerland and the life of the inhabitants of the mountains. 10 francs unbound, 14 francs bound. It has been translated into English.

MM. G. ROUY AND J. FOUCAUD have undertaken the preparation of a "Flora of France," intended to take the place of that of Grenier and Godron. In order to render the work as accurate and as complete as possible, they earnestly request the co-operation of those who are acquainted with the botany of any portion of the extensive region which their task will cover.

MESSRS. OLIVER AND BOYD publish the introductory lecture to the Agricultural Class at the University of Edinburgh, delivered by Prof. R. Wallace on October 22. The subject is, "American Cattle, and the American Export Trade in Beef and Live Cattle to Great Britain."

A PAMPHLET on "The Philosophy of Cycling," by Mr. W. K. Fulleylove, has been issued by Messrs. Curtis and Beamish, Coventry. It is the first of a "popular series of pamphlets on every-day science."

THE latest work issued in the series entitled "Smithsonian Miscellaneous Collections," is a valuable "Index to the Literature of Thermodynamics," by Dr. Alfred Tuckerman. The work is similar to Dr. Tuckerman's "Index to the Literature of the Spectroscope," published in the same series. All the titles are given in full in the author-index, but in the subject-index, to save useless repetition, only the authors and the places where their works are to be found are given—except in the case of books. The work has been brought down to the middle of the year 1889.

A USEFUL summary of progress in mineralogy and petrography in 1889 is presented in the form of a pamphlet compiled by Mr. W. S. Bayley (Waterville, Me.). It consists of a series of monthly notes which appeared originally in the *American Naturalist*.

THE Frankfort publisher H. Bechhold is issuing what promises to be a valuable "Handlexikon" of the natural sciences and of medicine. The editors are A. Velde, W. Schauf, V. Loewenthal, and J. Bechhold. Especial attention is paid to the practical applications of the sciences.

THE seventh volume of the Proceedings and Transactions of the Royal Society of Canada for the year 1889 includes, among other papers, the following: the cartography of the Gulf of St. Lawrence, from Cartier to Champlain, by W. F. Ganong; trade and commerce in the Stone Age, by Sir Daniel Wilson; expeditions to the Pacific, by S. Fleming; notes on mathematical physics, by J. Loudon; on the variation of the density with the concentration of weak aqueous solutions of certain salts, by J. G. McGregor; on new species of fossil sponges from the Siluro-Cambrian at Little Metis on the lower St. Lawrence, by Sir J. W. Dawson.

MR. C. C. VEVERS, Leeds, has published an illustrated catalogue of photographic apparatus, materials and catalogues, and optical lanterns and accessories.

MESSRS. R. FRIEDLÄNDER AND SON, Berlin, have just issued two catalogues of books which they have for sale, one relating to comparative anatomy, the other to *Arachnida*, *Myriopoda*, *Crustacea*, and *Rotatoria*.

BY authority of the Consul-General of Uruguay, London, a catalogue has been issued of the minerals from Uruguay shown at the recent International Exhibition of Mining and Metallurgy at the Crystal Palace. Associated with the catalogue are various allied documents, one of which is the mining code of the Republic.

COLONEL HOLABIRD, of Los Angeles, has lately returned to San Francisco from an exploring expedition in the cañons of Colorado. He penetrated districts never before explored, and found in an almost inaccessible cañon 100 miles north of Williams, and near the Grand Cañon of the Colorado, the Yava Supai tribe of Indians, who had never seen any white man, except Lee the Mormon, who was shot for the Mountain Meadows massacre. Colonel Holabird, in relating his experiences to a correspondent of the *New York Tribune*, said:—"These Indians are of the Apache family, but of ancient origin. The men are magnificent specimens. The valley in which the tribe has lived for many years in seclusion has only two ways of approach. It contains 2000 acres, and is inclosed by almost perpendicular walls 4000 feet high. We travelled over 15 miles along a cañon—a lifeless country. Suddenly we came to two boiling springs under cotton-wood trees. From these springs a river starts, which winds its way through a luxuriant valley. The water in the river is clear as crystal, and so strongly impregnated with lime that it petrifies everything it touches. There are three immense cataracts in the cañon. These look as if centuries ago a huge cotton-wood tree had fallen across the stream and lodged. Mosses, ferns, and creepers formed a barrier. All these have been turned to limestone. The grass caused the deposit to increase until the barricade extended across the cañon, making a fall of 250 feet. Along the front of these high cataracts, limestone ridges have formed 20 to 50 feet one above the other. Over all these the water falls like a sheet of glass. Underneath, between the ridges, thousands of plants, with flowers in full bloom, are seen, while millions of humming-birds dart in and out. The chief of the strange tribe is an old man of sixty—'Captain Tom.' I found these Indians in a starving condition, subsisting on berries and grass-seed. I appealed to the Government for them, but the Indian Department said it could not help wandering people."

THE November number of the *American Journal of Science* contains an account of the preparation of pure metallic cadmium, by the process of distillation *in vacuo*, recently carried out by Mr. E. A. Partridge in the laboratory of the University of Pennsylvania. The successful experiments described a few months ago by Messrs. Morse and Burton, in which it was shown that metallic zinc could be obtained in a state of purity by distillation at a high temperature in a vacuum constantly renewed by means of a Sprengel pump, led Mr. Partridge to make a similar attempt in the case of cadmium, with the ulterior purpose of utilizing such a sample of the pure metal for a redetermination of its atomic weight. The process has proved perfectly successful, and yields a metal of such purity that even spectroscopic examination fails to detect any traces of admixed foreign metals. The retorts employed were of glass—naturally of the hardest kind that could be procured. They were made of tubing of 20–25 mm. diameter, and at a distance of about 11 cm. from the closed end were drawn out into a neck of 12 mm. diameter, through which the volatilized metal passed into the receiving portion of the tube. This latter portion was finally drawn off in such a manner that it could be tightly connected with a treble-fall Sprengel pump. About a hundred grams of cadmium were introduced into the retort before drawing off, and after the latter operation had been performed the apparatus was exhausted by means of the pump, which was kept working during the whole period of the distillation. The retort was then heated in the combustion furnace in which it was supported, the temperature being so regulated that most of the liquefied metal ran back into the retort, only the more volatile vapours passing through the neck into the receiver. The distillation was continued until about sixty grams of metal had passed over, the operation lasting about an hour. The volatilized cadmium condensed partly in the bottom of the receiver in the form of a bar, and partly upon the upper portion and sides in the form of brilliant perfectly-developed crystals. The product was redistilled in a similar manner in order to minimize the risk of traces of foreign metals being carried over. The precaution, however, appears to be unnecessary, for the residue left after re-distillation of the greater portion was found to contain no trace of impurity when examined spectroscopically. The atomic weight of cadmium was determined by three distinct methods, the salts employed being prepared from this redistilled metal. In the first series the loss of weight on converting the oxalate into the oxide by ignition formed the basis of calculation, in the second series the loss of weight on converting the sulphate into sulphide by ignition in a stream of sulphuretted hydrogen, and in the third series the loss brought about on similarly converting the oxalate into sulphide. The mean values obtained for the atomic weight, when $O = 16$, from ten experiments in each series were respectively 111·80, 111·79, and 111·80. The final value deduced from the whole of the experiments is thus 111·8.

THE additions to the Zoological Society's Gardens during the past week include two Squirrel Monkeys (*Chrysothrix sciurea*) from Guiana, presented by Mr. E. Leech; a Brown Bear (*Ursus arctos*) from Russia, presented by Mr. W. H. Stuart; an English Wild Cow (*Bos taurus*, var.) from Bangor, North Wales, presented by Mr. G. W. Assheton-Smith; two Masked Weaver Birds (*Hyphantornis personata* ♂ ♀) from Abyssinia, a Short-winged Weaver Bird (*Hyphantornis brachyptera*) from Africa, presented by Commander W. M. Latham, F.Z.S.; a Viverrine Cat (*Felis viverrina*) from India, a White-crested Touracou (*Corythaix albo-cristata*) from West Africa, deposited; a —— Shrike (*Lanius lahtora*) from India, purchased.

OUR ASTRONOMICAL COLUMN.

MEASURES OF LUNAR RADIATION.—The Proceedings of the American Academy of Arts and Sciences (vol. xxiv.) contains an account of some measures of lunar radiation made by Mr. C. C. Hutchins by means of a new thermograph. This instrument consists of a single thermal junction of nickel and iron placed in the focus of a small concave mirror. The author finds that the condensing mirror fulfils the functions of multiplied junctions, while the single union rapidly attains thermal equilibrium. A comparison was made between the thermograph and a thermopile of forty-eight couples, the result being that the former was found about twelve times as sensitive as the latter. Measures of the radiating power of some rocks, mostly of volcanic origin, show a remarkable uniformity. If the radiation from a blackened surface of quartz be taken as 100, the lowest radiating power is possessed by common white pumice, and is represented by 71·3. The temperature at which the measures were made was near 100° C. The measures of lunar radiation were made with an arrangement similar to that of a Herschel's telescope with the thermograph in place of an eye-piece. The results of the experiments indicate that the heat which our planet receives from the moon is to that of the sun as 1 is to 184,560. Some observations were made during the lunar eclipse of January 28, 1888, for the purpose of determining whether our atmosphere allowed radiations from the heated lunar surface to pass through it. When the moon was in the penumbra, the reading of the galvanometer scale was 254·4, nineteen minutes before totality it was 11·2, eight minutes before totality it was 7·3, and the mean of thirty readings taken during the total phase gave the value 2·09. The inference drawn from these observations is, that all but a minute portion of the rays from the lunar soil and rock are cut off by our atmosphere, for it seems impossible to conceive that a surface like that of the moon, upon which the sun has been shining for many days, should suddenly cease to radiate when the sun's light is withdrawn. A comparison of lunar rays with solar rays reflected from various rocks shows that the selective absorption by the rocks is altogether insufficient to explain the great absorption of the lunar rays observed during the eclipse. An attempt has been made to construct a curve representing the change of transmission of lunar rays by our atmosphere with changes in the altitude of the moon. The measures show that our atmosphere, at the ordinary pressure, transmits 89·25 per cent. of the vertical lunar beam.

THE STAR D.M. +33° 470.—The Rev. T. E. Espin announces, in *Wolsingham Observatory Circular*, No. 27, that this star (R.A. 11h. 28m. 16s., Decl. +33° 38′, 1855), magnitude 9·2, was observed on November 7 as 7·5 magnitude. Hence the star is probably variable. The spectrum is that of Group II.

THE NYASSALAND REGION.

ON Tuesday evening, at the opening meeting of the new session of the Royal Geographical Society, Mr. H. H. Johnston read a paper on his recent visit to the region lying between Lakes Nyassa and Tanganyika. While Mr. Johnston dealt largely with matters bearing on British interests and the industrial development of the region, he was also able to make additions to our knowledge of its geography. Mr. Johnston, in H.M.S. *Stork*, sailed up the Chindé mouth of the Zambesi, and for some distance up the Shiré River, where he was transferred to the Lakes Company's steamer *James Stevenson*. He visited the well-known station at Blantyre, then sailed up the lake to Karonga, the British station on the north-west shore of the lake. After bringing the hostile Arabs to terms, Mr. Johnston went on across the plateau to the south end of Lake Tanganyika, visiting, by the way, Lake Hikwa or Rukwa, first seen by Mr. Joseph Thomson on his first expedition into Africa. Of the navigation of the Zambesi, Mr. Johnston said :—

"The navigation of the Zambesi from its mouth to Vicente is by no means an easy matter to those unacquainted with the intricate windings of the river's navigable channel. The great stream, which is, on an average, three or four miles broad, is studded with islands and beset with sand-banks. Vast stretches of the river are covered by scarcely more than six inches of water. To the eye of a man accustomed to the study of great rivers, the existence of these shallows is at once apparent by the mirror-like calm of the water that covers them, and the warm, pinkish tone of the sandy bottom which subtly permeates the blue reflections of the sky. On the other hand, the course of the deep channel is marked by the swirling water, the tiny whirlpools, and the sharply-cut sides of the bank, which, instead of tapering off into the stream, look as if they had been recently sliced with a large knife. There is a crying need for what at present does not exist, or, if it does, is not known to the outside world—a good, accurate, and detailed chart of the course of the Lower Zambesi. Although the course of the deep channel varies and alters, as it does in all great rivers, it does not generally change so quickly but that a little careful supervision might easily keep such a chart up to date."

The following account of what is to be seen on the Shiré is of interest :—

"Continuing the ascent of the Shiré, we skirt the strikingly picturesque range of the Pinda Mountains, all jagged peaks and sugar-loaves, on the east, and the Matunda Mountains on the west, while in the far, far distance northwards there rise the vast dim outlines of higher and higher peaks, culminating in Mount Tshiperoni (or 'Clarendon,' as it was named by Livingstone). The scenery on this stretch of the Shiré is really very fine. In the foreground there are the serpentine windings of the broad river through the great Morambala marsh, which is here and there dotted by little lakelets of clear blue water, but for the most part covered with wide stretches of tall reeds. These reeds bear large heads of creamy-white flower-tufts, almost as big as those of the pampas grass, and as the wind blows across the marsh it sways the reeds into wave-like undulations, wherein the great white heads of blossom appear like fluctuating foam cresting the billows of shining green leaf-blades beneath. Rising above this white-flecked sea of glistening grass are the abrupt ranges of fantastically-shaped hills and mountains, which girdle in the Shiré valley with great semicircles of blue mountain wall. Occasionally a glaucous-green Borassus fan-palm rises on a column-like stem from an island in the river or a dry patch in the marsh. These landscapes are drawn in large traits, and their harmonies are simple, and not complicated by the admixture of any human habitation or cultivation. It is not until one is within a relatively short distance of the Ruo that the banks of the Shiré begin to be inhabited again, and the marsh yields to thin forest and plantations of maize, tobacco, millet, and pumpkins.

"A short distance above the Ruo one enters the Elephant Marsh, a district of great grassy flats, flooded occasionally when the Shiré overflows its banks, but ordinarily a dry level stretch of prairie dotted with pools of water.

"At the close of the dry season, when the tall grass has been burnt down, and there is little or no cover for the game to hide in, it is really a remarkable spectacle, as seen from the deck of a steamer, to watch the great herds of big animals wandering over these savannahs in search of the young verdure springing up amid the charred stubble of the old grass. With an opera-glass you may distinguish water-buck, gnu, buffalo, eland, pallah, reed-buck, and zebra, and occasionally some dark blue-grey blobs, much larger than the other specks and forms which are in their vicinity, turn out to be elephants. Occasionally a lion has been known to come down to the river and stare at the steamer, and on one or two occasions these beasts have actually been shot from the deck in passing. Both in the Elephant and Morambala marshes, and in the Upper Shiré, the hippopotamuses are a real source of danger and inconvenience to any boats of ordinary size which are not propelled by steam. The hippopotamuses are particularly dangerous at night, but even during the day they will deliberately chase and endeavour to upset boats and canoes which enter their domain ; and in the development of the Shiré navigation it is essential that the hippopotamuses should be mercilessly exterminated."

Mr. Johnston described as follows the fine country on the north of Lake Nyassa :—

"Here there are no fewer than nine perennial rivers, some of them of considerable volume, which descend from the lofty mountain ranges of Buntali, Wukukwe, and Ukinga, and enter the lake between Karonga and Parumbira Bay, the moisture which percolates from them through the soil giving the Konde plain an appearance of perpetual spring. The land at the north end of the lake is a veritable African Arcadia. You may walk for miles and miles through banana plantations ; then you may emerge on wide-stretching fields of maize and millet and cassava. All the oozy water-meadows are planted with rice ; but, above all, the great wealth of the country is in cattle, which, elsewhere by no means common in Nyassaland, thrive remarkably in the Konde district, and consequently milk and beef are cheap and abundant. The inhabitants of this happy land are a contented, pleasant-dispositioned folk, who knew no trouble until the Arabs sought to subdue them a few years ago."

From a geographical point of view probably the most interesting part of his paper was that describing his visit to the remarkably desolate region around Lake Rukwa lying on the south-east of Lake Tanganyika. Rising from the fertile plateau are the

Wungu Mountains, some 6000 feet high, and Mr. Johnston thus described what he saw on ascending them :—

"We looked down on what I thought at first was a very broad sheet of water, surrounded on three sides by high ranges of mountains. But by degrees, with the aid of a field-glass, I discovered that what appeared to be a spacious lake in reality consisted of a narrow contorted strip of water on the one side, and between us and the water a wide extent of absolutely flat plain, so uniformly covered with blue-grey forest that from those heights above it was hard to distinguish it by its colouring from the real lake. When I had taken a number of angles from our camp on the mountain crest, we began a most arduous descent from the heights into the plain below. As we descended, our impressions and forebodings became of a somewhat dismal character. Everything around us bore witness to the dearth of water. On the other side of the mountain range we had left a country in the fully beauty of spring, intensely green with the gentle showers of the commencing rainy season, but here on the slope facing Rukwa, the farther we descended the more arid the country became. At the base of the mountains we crossed a three-mile stretch of level plateau, covered with the dismal grey growth of innumerable thorn-trees, so gnarled and contorted in shape, and provided with such cruelly ingenious hooks and barbs and stiletto-like thorns, that they might have been the enchanted forest round some wizard's lair.

"This plateau came to a sudden and abrupt termination, and from its edge we made a precipitous descent along a blood-red path into a blood-red ravine, the sides of which were fantastically planted and festooned with clumps of purple-green aloes, and those weird candelabra euphorbias with grey spectral stems, the segmented stalks of which looked like the tails of innumerable scorpions. Down through the dark gloomy depths of this cleft of the earth we floundered, slipped, and fell into the gorge of a dry river, cut deeply in a winding channel between precipitous red walls, the sides of which were scoured and polished and striated as if by glacial action. There were scattered stagnant pools of water in the red, red rocks and sand, and water oozed from places in the river bed when our porters dug below the surface. The trees clinging to the sides of the ravine were emerald green, with a metallic-tinted harsh verdure. Evidently this dried-up stream had once been an important river and a powerful torrent, and nothing is more remarkable in the vicinity of Rukwa than to observe the traces of a once abundant rain supply, which, from some unexplained cause, has—so the natives say—suddenly ceased during the last two or three years, as though the country had been literally blasted by some terrible curse.

"Crossing the dry bed of this river we entered on another level stretch of country gently sloping northwards, its surface uniformly clad with a forest of grey thorn-trees, but with the ground at their bases bespangled in a strange contrast with gorgeous flowers, which were almost unaccompanied by leaves, just the vividly-coloured petals rising from the hard grey soil.

"These consisted chiefly of purple, yellow, and white anemones, arborescent lilies, with white star-like flowers springing from a grey branching stem, and great heads of pink crinums resembling the 'kafir lily' of South Africa.

"We passed an occasional dry water-course choked with grey-green life-in-death vegetation, and then at length reached a broader dried-up stream-valley, with shadier trees and a stockaded village, the first we had met with in the land. . . . As soon as we got out of the broad, shaded stream-valley where the village was situated, we entered the frying, blazing heat of the parched plain, and found ourselves in a white, light, bright hell of dazzling sunshine. The shadeless acacias with their cruel thorns, the dry yellow grass, and the yellow withered Borassus palms, in no way mitigated the pitiless glare of the vertical sun, while a raging wind, hot as the breath of a furnace, swept over the plain and burnt the skin of our faces, so that we felt as if we wore tight masks. Every quarter of an hour the wretched caravan had perforce to stop and pant under the thin film of shade which might descend from the skeleton branches of a dead tree. At length, after frequent halts and protestations from the sun-stricken men that they could go no farther, we saw ahead of us an emerald-green line in the grey wilderness, which marked the presence of water. This turned out to be a welling, brackish pool thronged with bulrushes and reeds, a kind of circular spring of overflowing water apparently connected with the lake by a long lane of rush-choked marsh, very distinct from the arid plains of baked mud. We camped here, where the scenery was a little less ghastly in its dead ugliness. The acacias exhibited a little green foliage among their thorns, and they were frequented by thousands of cooing doves, while the scanty bushes on the ground served as cover for many francolin and guinea-fowl. Game, in the shape of antelopes and buffaloes, was evidently abundant, and no doubt was attracted to the vicinity of this brackish pool by the flakes of salt which remained on the soil where the water had evaporated; and the game in its turn was followed by hyenas, lions, and vultures. The hyenas laughed and the lions roared outside our camp fires, and the next day I noticed many scattered fragments of bones and skulls in the vicinity, which were the relics of previous feasts on the part of these Carnivora.

"I was anxious to proceed direct to the lake from here, as we were only about three or four miles distant, but the Wuñgu people would not allow us to do so until we had first seen their Sultan, so we travelled in a north-easterly direction, always through this scorching, glaring wilderness, till we reached the bank of the Soñgwe River. Here I camped so that the men might be close to fresh water, but it appeared to us that even the water of the Soñgwe was brackish, though it was a running river. It seemed to have no effect in quenching one's thirst, and contained some irritating property which occasioned diarrhœa, and even dysentery. Leaving my men at the Soñgwe, I went with Mr. Nicoll and Dr. Cross to visit Mwinyi-Wuñgu, who lived about a mile from its banks in a stockaded town. I can hardly describe the heat of the atmosphere in walking thither; it was like passing through fire. When we got into the town, we eagerly crept under the shade of the overhanging eaves of the houses, which extended so near the ground, for the sake of coolness, that one had to get down on all fours to get under them."

As there was really a famine both of food and water in this dreadful wilderness, Mr. Johnston and his large party of men were compelled to hasten out of it, without his actually being able to get to the edge of the lake itself. What he has told us about this region makes us desirous of knowing more. It is a remarkable fact that, while in the Nyassa-Tanganyika plateau there had been no lack of rain, in the lake basin itself not a drop had fallen for three years.

THE BOTANICAL MYTHOLOGY OF THE HINDOOS.

At a recent meeting of the Anthropological Society of Bombay, Dr. Dymoke read a very interesting paper entitled "The Flowers of the Hindoo Poets," in the course of which he referred to the mythical conceptions which have gathered round trees and plants in the minds of the Hindoos. The ancient Eastern poets saw in the tree a similitude with the heavens and with the human form; in the "Gitagovinda" a comparison is drawn between the clouds and the thick dark foliage of the *Tamala*. These fancies gave rise to the numerous poetical myths concerning the tree of life, of knowledge, of the *Amrita* or Ambrosia, as well as those concerning cosmogonic and anthropogonic trees. The *Soma* or *Amrita* is represented as the king of plants, the eternal essence which constantly sustains and renews the life of plants and animals; it is the symbolical drinking of this eternal essence as a holy ceremony to which constant allusion is made in the Vedas :—

"We've quaffed the Soma bright,
And are immortal grown;
We've entered into light,
And all the gods have known."

—*Rigveda*, viii.

The Amrita appears in various forms in stories and legends. A famous poet says that the drop (*Svedavindu*) which fell into the shell became a pearl; in the mouth of the black snake it became poison; and in the flower of the plantain, nectar. Several plants bear this name, and are supposed to be endued with an extra particle of the eternal essence; among others, the *Neem*, on which account the Hindoos, on their New Year's Day, eat the leaves of this tree upon the supposition that the Amrita contained in them will insure longevity. In Hindoo flower lore the large black bee (*Buramara*) plays an important part: he is the inconstant lover who delights in gathering sweets from every flower. The queen of Indian flowers is the lotus: the Hindoos compare the newly-created world to a lotus flower floating upon the waters, and it thus becomes symbolical of spontaneous generation. The golden lotus of Brahminic and Buddhistic mythology is the sun, which floats in the waters which are above the firmament, like an earthly lotus in the deep blue stream below. From it distils the Amrita, the first manifestation of Vishnu. Brahma and Buddha (the supreme intelligence) were born of this heavenly lotus. Lakshmi, the Indian Venus, is represented sitting on this flower. The Hindoos see in the form of the lotus the mysterious symbol, *Svastika*. The allusions to this flower by Indian poets are innumerable. No praise is too extravagant for it; it is the chaste flower, and its various synonyms are bestowed as names upon women. The red lotus is said by the poets to be dyed with the blood of Siva that flowed from the wound made by the arrow of Kama, the Indian Cupid. The face of a beautiful woman is compared by the poets to a lotus blossom, the eyes to lotus buds, and the arms to its filaments. The bee is represented as enamoured of the lotus. Although a humble little flower, the *Tulasi* is almost as great a favourite as the lotus; it is addressed to the goddess Sri or Venus. The heart of Vishnu is said to tremble with rage if a branch of his beloved is injured. The plant must be gathered only for medicinal or religious purposes, such as the worship of Vishnu or Krishna, or the wife of Siva. It is a kind of amrita, symbolical of the eternal essence; it protects the worshippers and gives children to women. The plant is often worshipped as a domestic deity, and its branches are placed on the breasts of the dead. The Champa is chiefly celebrated for its overpoweringly sweet odour and golden colour; so strong is its perfume that the poets affirm that bees will not extract honey from it; but they console it for this neglect by dedicating it to Krishna, who loves garlands of yellow flowers as becoming to his dark complexion. One of the greatest favourites of the poets is the Asoka; its flowers, which are yellow when they first open, gradually change to red. In March and April it is in its glory, and at night perfumes the air with its delicate odour. The tree is the *kul* or anthropogonic tree of the Vaisya caste, who call it Asupala. The Kadamba (*Anthocephalus cadamba*) is sacred to Kali or Parvati, the consort of Siva; it has many synonyms, such as "protecting children," "dear to agriculturists," &c. It blossoms at the end of the hot season, and its night-scented flowers form a globular orange-coloured head, from which the white-clubbed stigmas project. The flowers are fabled to impregnate with their honey the water which collects in holes in the trunk of the tree. In Delhi the goldsmiths are fond of imitating the flowers. The well-known prickly gold beads so often seen in Delhi jewellery are meant for kadamba flowers. In this part of India the Marathas will not gather the flowers for profane purposes as it is their anthropogonic tree. The Kadamba Rajas claim their descent from it, as recorded in the following legend:—"After the destruction of the demon Tripura, a drop of perspiration fell from the head of Isvara into the hollow of a kadamba tree, and assumed the form of a man with three eyes and four arms. He became the founder of Vanavasi or Jayantipur." There are other versions of the story, but all agree in connecting the origin of the family with this tree, a branch of which is necessary to represent the Kai at a Marathi marriage ceremony.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At the biennial election to the Council of the Senate held on November 7, the following were nominated (the * indicates retiring members):—Heads (2 seats)—*Dr. Atkinson, Clare, *Dr. Ferrers, Caius, Dr. Hill, Downing; Professors (2 seats)—*Dr. Cayley, Trinity, Dr. Sidgwick, Trinity, Prof. Ryle, King's; Members of the Senate (4 seats)—*Dr. D. MacAlister, St. John's, Dr. Forsyth, Trinity, *Mr. Whitting, King's, Mr. R. T. Wright, Christ's, Mr. E. H. Morgan, Jesus, Mr. C. W. Moule, Corpus, Mr. C. H. Prior, Pembroke. The voting was as follows:—Dr. Ferrers, 184, Dr. Atkinson, 137; Dr. Cayley, 191, Dr. Sidgwick, 127; Dr. D. MacAlister, 158, Mr. Whitting, 156, Dr. Forsyth, 153, Mr. Wright, 117. These were elected. Dr. Hill received 109 votes, Prof. Ryle, 103, Mr. Prior, 111, Dr. Lea, 82, Mr. Morgan, 81, Mr. Moule, 71. The newly-elected members hold office for four years. The result is interpreted as a gain for those who favour the modern development of the University.

It should have been stated that the election of Fellows referred to in our last number took place at St. John's College.

Mr. Frank McClean, M.A., of Trinity College, has offered securities of the value of £12,000 to be held in trust for the University by Trinity College, for the purpose of founding three "Isaac Newton Studentships" in Astronomy, Astronomical Physics, and Physical Optics. The students are to hold their emoluments for three years, to be Bachelors of Arts, and of high mathematical attainments.

R. S. Cole, B.A., of Emmanuel College, has been appointed a Junior Demonstrator of Physics at the Cavendish Laboratory, in the place of Mr. L. R. Wilberforce, promoted to be Demonstrator.

The General Board of Studies propose the foundation of an additional Demonstratorship in Physiology, under Prof. Michael Foster, without stipend from the University Chest.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Microscopical Society, October 15.—Dr. C. T. Hudson, F.R.S., President, in the chair.—Mr. G. F. Dowdeswell's note on a simple form of warm stage was read, and the apparatus exhibited.—The President said he had with great regret to record the deaths of two honorary Fellows of the Society—Prof. W. Kitchen Parker, F.R.S., and Mr. J. Ralfs. In place of these two gentlemen Dr. H. B. Brady, F.R.S., and Prof. W. C. Williamson, F.R.S., were nominated.—Mr. Mayall said he must ask the indulgence of the meeting to enable him to clear himself from possible ambiguity. In notifying the fact that at the first photographic trials of the new objective of 1·6 N.A. the visual and actinic foci had been found by Mr. Nelson and himself to be not coincident; and that when the objective was returned to Jena immediately after, Dr. Czapski found the foci were coincident; he had hazarded what he had imagined would appear a mere playful admission of the state of general puzzlement of both sides by suggesting that "the transit of the objective from London to Jena had somehow got rid of the 'chemical' focus." That sentence had unhappily been construed both in England and abroad into a reflection upon the good faith of Dr. Czapski, or Dr. Abbe, or the firm of Zeiss. Whatever blame was due to himself for the ambiguity of the expression, he must, of course, accept. At the same time he thought the Society would be interested to learn that upon his conveying his explanation to Dr. Czapski and Dr. Abbe, those gentlemen had expressed their complete satisfaction with it. He believed that the existence of a "chemical" focus was probably due to a slight difference in the adjustment of the front lens, especially, as Dr. Abbe had pointed out, in view of the fact that with an objective of such large aperture the colour correction was, as it were, "balanced on a needle-point" in the matter of an alteration in the distance of the front lens from the posterior combinations; and that a very minute alteration in that distance, though producing no perceptible difference in the visual image, was quite competent to lengthen or shorten the focus of the violet rays to such an extent as to exhibit a "chemical" focus non-coincident with the visual focus when tested photographically.—The President gave formal notice that a special general meeting would be held in the Library at 5 p.m. on Wednesday, October 22, for the purpose of considering alterations in the byelaws, the terms of which he read.—Mr. G. C. Karop exhibited and described an improved students' microscope, made by Swift and Son. The new instrument embodied Mr. Nelson's "horseshoe" stage for convenience of readily seeing the condenser, and for estimating by the touch the approximation of the focus on the slide, and on which the Mayall mechanical stage was easily applied, together with a centring sub-stage focussed by sliding on the tail-piece, the whole of superior workmanship and design, and supplied at a moderate outlay.—Prof. J. W. Groves communicated a note by Mr. P. C. Waite on a new method of demonstrating intercellular protoplasmic continuity. A specimen in illustration was exhibited.—Mr. J. D. Aldous exhibited some early forms of microscope slides made of boxwood, similar to those formerly made of ivory, with the objects between pieces of talc.—The President called attention to some original drawings of a new Rotifer by Mr. W. B. Poole, of South Australia: also to a specimen of *Œcistes mucicola* exhibited by Mr. G. Western.—Mr. E. M. Nelson exhibited upon the screen a series of thirty-one photomicrographs, which he described.—Dr. H. B. Brady's paper on a new type of Foraminifera was taken as read.

—Dr. Maddox's paper on the structure of Spermatozoa was postponed until the next meeting in consequence of the lateness of the hour.

PARIS.

Academy of Sciences, November 3.—M. Duchartre in the chair.—Notice of the works of M. Pierre de Tchihatchef, by M. Daubrée. M. de Tchihatchef died at Florence on October 13. He was born at St. Petersburg in 1815, and elected a correspondent of the Academy in the Geographical Section when about thirty years of age. An account is given of his many scientific works.—A photo-chronographic apparatus that may be used to analyze every kind of motion, by M. Marey. A photographic film is caused to move across the focus of the lens of a camera. The motion is imparted by an electric motor, and with the arrangement described the film may be arrested fifty times a second for the production of as many views of the object being photographed. A plate giving six views of a trotting horse accompanies the note.—On the relation of gangrenous septicæmia to lock-jaw, with special reference to the associations of virulent microbes, by M. Verneuil. From a series of surgical and chemical experiments, the author is led to believe that the co-existence in man of certain forms of mortification and lock-jaw is not accidental, but results from the simultaneous production in the wounds of two microbes well known to Pasteur and Nicolaïer.—On the movements of a double cone, by M. A. Mannheim.—On the periodic functions of two variables, by M. Appell.—On a particular case of Lamé's equation, by M. V. Jamet.—Undulatory pressures produced by the combustion of explosives in a closed vessel, by M. Vieille.—On Bunsen's photometer, by M. R. Boulouch.—The rotation of the earth on its axis produced by the electro-dynamic action of the sun, by M. Ch. V. Zenger. The author has caused a hollow sphere to rotate under the action of the two poles of a Wimshurst machine, and thence argues that the planetary motions in our solar system have an electro-dynamic origin.—Action of borax in alkaline developing baths, by M. P. Mercier.—On the affinities of iodine in the dissolved state, by MM. Henri Gautier and Georges Charpy. The authors have studied the chemical behaviour of solutions of iodine in different media. Shaking the solutions with a lead amalgam, they find the colours of the mixture of iodides obtained in each case—that is, the proportions of the iodides of lead and mercury respectively—depend on the kind of solution employed.—On the γ-cyanoacetoacetic ethers and the hydrochlorides of the corresponding imides, by MM. A. Haller and A. Held.—Researches on the conditions of the reactions of the isopropylamines: limit to the production and development of propylene, by MM. H. and A. Malbot. The authors have studied (1) the action of isopropyl iodide on very concentrated aqueous ammonia in equi-molecular proportions, at the ordinary temperatures; (2) the same at 100°; (3) the same above 100°; (4) the action of isopropyl chloride upon aqueous ammonia at 140°. From the results of experiment, they have summarized their conclusions as to the character of these reactions between aqueous ammonia and isopropyl iodide and isopropyl chloride.—The Hanneton parasite, by M. Le Moult.—On certain formations on copper and bronze, by M. Raphael Dubois. The author has observed and studied some white mycelium flakes, very similar to those of *Penicillium* and *Aspergillus*, in solutions of concentrated copper sulphate neutralized by ammonia and used for the immersion of the gelatine plates employed in photogravure. Similar formations have been observed on bronze.—On some rocks from the Lunain valley, supposed to have been used to polish stone implements in Neolithic times, and on the action of water in the Stone Age, by M. Armand Viré.—On the formation of abrupt escarpments of earth that interrupt the slope of valleys in the north of France, where they are known as *rideaux*, by M. A. de Lapparent.—Experimental contribution to the history of the dendrites of manganese, by M. Stanislas Meunier.

KOCH'S CURE FOR CONSUMPTION.

DURING the last week Koch has made a further communication regarding his treatment of tuberculosis, which has been received with intense interest and perhaps with a certain amount of disappointment. For he has described his mode of applying the new remedy with sufficient accuracy to allow medical men to use it in the treatment of their patients, but he has left us still completely in the dark regarding the nature of the remedy itself.

A certain quantity of the remedy can be obtained from Dr. Libbertz, who has undertaken its preparation with the co-operation of Dr. Koch himself and Dr. Pfühl, but their stock is at present small, and larger quantities will not be obtainable for some weeks. In exercising this reserve regarding the nature of the remedy he employs, Dr. Koch has probably done very wisely, for it is evident that the substance he uses is very powerful and any inaccuracy or imperfection in its preparation might prove injurious to patients, and bring discredit upon the mode of treatment.

The remedy is a brownish, transparent fluid which is much too strong for use until it has been largely diluted with water. The diluted solution is applied by subcutaneous injection. There is a remarkable difference between the action of this remedy upon guinea-pigs, healthy men, and phthisical patients. Two cubic centimetres of the undiluted liquid produces no sensible effect when injected under the skin of a guinea-pig; but, calculated by body weight, the fifteen-hundredth part of this quantity produces cough, difficulty of breathing, sickness, vomiting, and fever, lasting for about twelve hours, in a human being. The presence of tubercle in the organism appears to render it extremely susceptible to the action of the remedy, for while the hundredth part of a cubic centimetre, *i.e.* one twenty-fifth part of the dose just mentioned as producing fever in healthy subjects, has no effect upon them, it will cause high fever along with coughing and sickness in tuberculous patients. Nor is this to be wondered at, for the remedy exerts its action upon the tissues which have been infiltrated by the tubercle bacillus and not upon the bacillus itself. It causes these tissues to die and be thrown off along with the bacilli they contain. This process is accompanied by fever, which the dose of the remedy used would not produce in health. In consequence of this the remedy may be used as a means of ascertaining the presence of tuberculosis as well as of curing it. If it causes more fever than it ought to do, in a doubtful case of phthisis, the presence of tubercle may be assumed, and when it ceases to produce fever in a patient under treatment the cure may be regarded as well-nigh complete. The effect of the remedy upon the diseased tissues can be seen in cases of lupus, where the tubercle bacillus infiltrates the skin instead of attacking the lungs as it does in consumption. A few hours after the remedy has been injected into the skin of the back, the spots of lupus on the face, far away from the seat of the injection, begin to swell and redden, and then become brown and dead, while the healthy tissue around becomes red and inflamed. The spots then become converted into dry crusts, which fall off in one or two weeks, leaving a clean red cicatrix behind. This result is very much like that produced by the direct application of a strong arsenical paste to the lupus spots. The tubercle bacilli weaken the vitality of the tissues which they infiltrate. The arsenic finishes the process they have begun, and kills the weakened tissues altogether, while it does not destroy the healthy tissues, and the once diseased but now dead part withers up and falls away from the living and healthy parts around. But arsenic can only do this when applied to the lupus in quantities sufficient to poison the patient many times over if it were absorbed into the blood, and consequently is quite out of the question as a cure for tuberculosis. Koch's remedy, on the other hand, seems to seek out tubercular tissue wherever it may be, and almost certainly produces changes in tubercular lungs and joints similar to those in lupus spots, although its action cannot be seen in the former as it can be in the skin. The fact that the new remedy does not destroy the tubercle bacilli, but only the tissues in which they are embedded, is distinctive of Koch's new method, which promises to effect a radical change in the treatment, not only of tubercle, but of many other diseases.

Since the discovery by Metschnikoff six years ago that the cells of the blood and tissues can eat up and digest the bacilli which constitute the germs of many diseases, the view has been constantly gaining ground that recovery or death in infective diseases is simply a question of the victory of the cells of a living organism or of the bacilli by which they have been attacked. In seeking for methods of cure men have tried either to find a way to weaken and destroy the bacilli, or to strengthen the resisting power of the tissues. When an organism is attacked by a new disease, it succumbs like an untrained army in the presence of an enemy. But the tissues appear to acquire a power of resistance, and if the first attack be recovered from, the organism is in many instances insusceptible to subsequent infection, as is shown in the case of small-pox, whether this has been accidentally acquired or intentionally inoculated. But an army may be trained to military tactics by sham fights instead of actual warfare, and the cells of an organism may become endowed with the power of resisting any infection, however virulent, by successive inoculations of a virus, weak at first but gradually increasing in power. This was the plan followed by Pasteur in his inoculations for anthrax. In these he employed at first anthrax bacilli so weakened by cultivation in an unfavourable medium that they produced nothing more than a slight indisposition, and then a virus less and less weakened until the virus of full strength could be successfully resisted. This process was one of protection rather than cure, but in his researches on rabies Pasteur turned his genius to the discovery of a means of cure. As he informed the Commission which went from this country to report on his method, he was himself not exactly aware how he arrived at his mode of treatment, but the conclusion had formulated itself in his mind that the disease produced a substance which was a protective against its own action. The treatment which he based on this conclusion has been so successful as to lead to many attempts to separate disease-germs and protective. These attempts have hitherto been fruitless in the case of rabies, but have been successful in other diseases. By cultivating disease-germs in a suitable liquid, and afterwards killing the germs themselves by heat, or removing them by filtration through porcelain, solutions have been obtained quite free from germs, and containing only the substances they have formed during their life and growth. Such solutions have been shown by M. Pasteur's pupils and others to have the power of protecting from septicæmia, anthrax, typhoid fever, and diphtheria; and Prof. S. Dixon, of Philadelphia, has succeeded in rendering animals resistant to inoculation with tubercle by previously inoculating them with the products of growth of the tubercle bacillus.

Most interesting experiments on the nature of these protective substances have been made by Wooldridge, Hankin, and Sydney Martin, who have shown that they are probably either globulins or albumoses rather than alkaloids, although Martin has obtained an alkaloid which produces all the symptoms of anthrax, and possibly may protect against it.

Koch's direction that his new remedy is to be prescribed under the name of paratoluid seems to indicate that it belongs to a class of bodies more nearly akin to alkaloids than to albumoses. Para-acet-toluid has been investigated by Jaffe and Hilbert, and found, like Koch's remedy, to be innocuous to the lower animals. It is possible that the new remedy may belong entirely to that class which has furnished us lately with so many valuable antipyretics and analgesics. But it seems more probable that it consists partly at least of a lymph containing the products generated by some microbe. One's first thought would naturally be that the substances formed by the tubercle bacillus itself would be chosen by Koch for curative as they have been by Dixon for protective purposes. But tubercle differs much from many other infective diseases, for anthrax, typhus, scarlet fever, or measles, run a definite course, and if they do not kill the patient at once, they protect him from a subsequent attack. But the attack of hectic fever which daily recurs in a patient suffering from phthisis confers no protection on him at all, but rather hastens the progress of the disease to a fatal termination.

The case is sometimes different when disease due to another microbe attacks a patient suffering from some form of tuberculosis. Thus lupus has been seen to shrivel and die after an attack of erysipelas or measles, and peritonitis, supposed to be tubercular, has disappeared during recovery from diphtheria. Judging from the resemblance between the effects of Koch's remedy and those of erysipelas, measles, or diphtheria, we should be inclined to suppose it to consist of a filtered culture of the germs of one of these or of some such infective disease, probably mixed with some kind of paratoluid.

It may perhaps seem idle to speculate on the composition of a remedy which its discoverer will probably describe fully ere long, but it must be remembered that tuberculosis, though one of the most frightful scourges of mankind, is not the only ill that flesh is heir to. There are others, with a less mortality perhaps, but even more feared by the sufferers themselves, and we may trust that the lines of research just indicated, whether they be exactly those on which Koch has been working or not, may lead to the discovery of certain cures for scarlet fever, diphtheria, gummata, and that most dreaded of all—cancer.

T. L. B.

THE CHEMISTRY OF IRON AND STEEL MAKING.

The Chemistry of Iron and Steel Making. By W. Mattieu Williams, F.C.S., F.R.A.S. (London: Chatto and Windus.)

THIS work differs materially from the ordinary technological text-books with which we are so familiar. Throughout it is evident that the author has thoroughly utilized his varied experience and great ability to their fullest extent, resulting in the production of a mass of suggestive information valuable to the ordinary student, and affording matter for reflection, even to those who have for years made the chemistry of iron and steel a specialty.

The introductory portion of the work is interesting, but chiefly briefly historical; the same may be said as regards chapter ii., on the ores of iron, which includes some speculations on the possible meteoric origin of iron. The wide diffusion of iron in the form of dust is quoted as indicating in part at least the meteoric origin of the metal.

Chapters iii. and iv., on reduction and dissociation, fluxing, roasting, and calcination, are thorough, giving concisely and forcibly the necessary knowledge in a manner well worthy of imitation in more pretentious works. The author's study on the analogy of dissociation to evaporation, commencing with water, followed by illustrations of the dissociation of the metals from their oxides, &c., shows that he not only clearly understands his subject, but also has the faculty of communicating his ideas clearly to others.

It is difficult to do justice to chapters v. and vi., on the blast-furnace, without entering into details which would here be out of place. The descent of the charge in the blast-furnace is first discussed, and the importance of clear ideas as regards the *rationale* of blast-furnace charging is insisted upon. It is not a simple process: (1) the heterogeneous impurities of the ore have to be removed; (2) the iron must be reduced to the metallic state; (3 and 4) the reduced metallic iron must be fused, as also the earthy impurities. All must proceed in due sequence. A definite statement of the problem of modern iron smelting must be before us ere we can follow rationally the reactions which occur. The evolutionary process from the old bloomeries or Catalan forge, next the small blast-furnace up to the huge structures of to-day is clearly set forth. Credit is also given to the practical worker, who, the author acutely remarks, must have possessed more practical scientific knowledge than we have been inclined or able to perceive.

The apparent irrationality of the modern system of smelting, by which iron ore is not only reduced to the metallic state, but the resultant metal becomes loaded with silicon and carbon, &c., is fairly discussed. It is shown that although what is termed the direct process, *i.e.* the simple reduction of the metal from its oxide, may be so conducted as to produce a nearly pure wrought iron, yet such methods are not economical, and are of limited application.

The direct process (p. 85) demands rich ores; a great expenditure of fuel is incurred; simple and direct as it appears, a greater cost is involved; on the whole, it is better to resort to the ordinary purification of crude cast-iron by the puddling process. The relative merits of the direct process *versus* the ordinary practice of smelting and puddling, are, however, still under consideration. Recent investigations, combined with improved methods, indicate that at any rate in some localities the direct process may be advantageously applied. The modern blast-furnace is clearly described; the form, viz. a circular column swelling in diameter at both extremities, is commented upon, and sound reasons are adduced why this approximate form must be adhered to. Next (pp. 88–93) follows a brief but graphic picture of the behaviour of the mixed charge of ore, coke, &c., during its descent, from the charging to the final fusion of the iron in the crucible or hearth, which deserves careful reading.

The preliminary preparation of ores, *e.g.* drying, roasting, &c., previous to charging into the furnace, is strongly and rightly advocated. Iron manufacturers, however, are averse to anything entailing extra trouble and labour. It is the general opinion that, on the whole, little is gained practically, although theoretically the ordinary practice of charging raw material must, as the author says, entail considerable uncertainty during the subsequent smelting. We agree with Mr. Williams that the reactions of carbonic oxide and carbonic acid gases in the blast-furnace are even now not thoroughly understood; further, the part which solid carbon plays in the direct reduction of ores seems to us still somewhat mysterious. It is admitted that, when using soft coke, carbonic acid may be deoxidized, forming carbonic oxide. This occurs in the upper region of the furnace, and it is quite as probable that ore in contact with carbon may be also directly reduced in this part of the furnace. We have ourselves ascertained that, when intimately mixed oxide of iron and carbon are heated together, the reduction commences at a lower temperature than is usually supposed.

The theory of puddling is well discussed, and the working processes are lucidly explained. In addition the chemical reactions whereby purification is effected are given; also, as regards the elimination of sulphur and phosphorus, the work of Percy, Bell, and many others is ably summarized. The author also quotes his own results, derived from his experience and study, which, however, are not always quite in accordance with accepted ideas, but which nevertheless should be carefully considered.

Many pages are devoted to the question of what is steel; also fallacies concerning steel. Previous to the introduction of the Bessemer process, steel might be defined as a compound of carbon and iron, capable of being hardened, tempered, and welded. Steel containing $\frac{3}{4}$ per cent. of carbon was termed mild steel. The author states that by the Bessemer process steel is made as low as $\frac{2}{10}$ per cent. of carbon; really, however, large quantities of Bessemer steel, or rather metal are now cast with only $\frac{1}{10}$ per cent. carbon. The author does not mention this. One gathers that there is only one true steel, *i.e.* a compound of iron and carbon free from other constituents.

The old definition of steel, *i.e.* a compound of iron and carbon, is as true as ever, when applied as in the past to a material used for special purposes, viz. tools with cutting edges, &c.; but it would be perhaps more rational to say that the Bessemer product cannot in this sense be termed steel at all. It may be granted that a true steel is simply composed of iron and carbon, but such a material has its own particular uses; and should not be compared or confounded with the Bessemer product, where the very properties of being tempered, hardened, &c., with facility must be avoided. In proof of this it has recently been shown that Bessemer metal may be improved by the addition of small quantities of silicon, nickel, or even copper; also that for certain purposes a large quantity of manganese may be added to iron with advantage. Indeed, a well-known writer has gone so far as to hint that carbon may be eliminated altogether, and some other element advantageously substituted. It appears, therefore, that the author's definition of what is steel may in one sense be strictly true, yet may be inapplicable to the Bessemer product for the above reasons.

In chapter x., on fallacies concerning steel, the author reiterates that steel can only be manufactured from pure iron, showing clearly enough that many novel, promising processes have failed solely from the non-recognition of the necessity of freeing crude iron from certain objectionable elements.

The hardening, tempering, and testing of steel under varying conditions, also the cementation process, are discussed; as briefly put, they may be considered complete. The author's own investigations should be carefully studied. It is suggested that during the cementation process carbon itself is not transmitted, but that a soaking in of iron carbide occurs. A film of carbide is first formed on the surface of the metal; this unites or alloys with the layer of iron below; a lower carbide is formed which reacts in like manner, and so on to the interior; and borings taken from next to the surface, also at different depths below, indicate, as might be expected, varying properties of carbon. The gases occluded in the charcoal used for cementation appear to assist the reaction of carbon on iron. The writer has been informed that charcoal thus used becomes in time inert, having apparently lost occluded gas. Some metallurgists assert that carbon does not combine directly with iron, but recently this has been questioned, and it has been experimentally demonstrated that iron may combine with pure carbon. Discussing the *rationale* of cementation, it is suggested that possibly iron at a welding heat is really not a solid, but rather in a viscous, semi-fluid condition like sealing-wax or melted glass. Iron is thus rendered more porous to gases, and probably solids are thus absorbed. The experiments of Graham and others on the absorption of gases by iron seem in conformity; in fact, this absorption may be termed a species of cementation.

The Bessemer process is well described and its early history given; a clear explanation is afforded showing how the inventor's early anticipation that wrought or malleable iron could be manufactured direct was not realized, although the chemical reactions, viz. oxidation, &c., were similar in degree to those in the puddling furnace and refinery. Credit is given to Mr. R. Mushet, who first suggested the addition of spiegeleisen to the blown metal, thus converting a worthless material into the valuable material now termed Bessemer steel.

The chemical reactions of both the Bessemer and puddling processes are compared, and the necessity of using with the former a pure pig-iron free from sulphur and phosphorus clearly demonstrated. The primary reason given by Mr. Mushet for the addition of spiegel was that blown Bessemer metal contained an excess of oxygen in some form or other; and the triple compound of iron, manganese, and carbon was added with the sole object of removing oxygen, a slight excess being added to insure the necessary proportion of carbon. The author appears to have laid sufficient stress on this; the primary cause, according to Mr. Mushet, of the redshortness of the metal; and which is even now a difficulty, for it is known that oxygen cannot be entirely eliminated without the addition in many instances of an injurious excess of spiegel—the addition of silicon, and recently aluminum has been suggested, both favouring the elimination of oxygen.

P. 294. Viewing the Bessemer method as a purely chemical process, it is urged that chemical compounds, or solutions in admixture, will not always arrange themselves in the order of their chemical affinity; where a transfer of constituents can produce a solid compound, such transfer occurs as though the physical attraction of cohesion overpassed that of chemical affinity. Following this general rule, on which all chemical analyses are based, silicon (forming a solid) must go first; carbon follows; the rapid disappearance of manganese is due to its great affinity for oxygen; it also forms a solid silicate of manganese. Sulphur and phosphorus are not eliminated, owing doubtless to the small quantities present. This is hardly conclusive. The author says but little of the rapidity of the chemical reactions; and does not appear to have realized that ordinary chemical reactions may be modified in consequence of the abnormally high temperature attained during the Bessemer blow.

The influence of what may be termed mass has not been noticed; chemical affinities may thus be modified. Of two bodies in solution one may be greatly in excess of the other; on adding a precipitant it will be found that the element in excess is first precipitated, although the chemical affinity may be about the same or even greater for one element than the other. Barium sulphate is slightly soluble in acidified water, and it will be found that either barium or sulphuric acid may be precipitated at will by adding to the solution for the former a slight excess of sulphuric acid; for the precipitate of sulphuric acid it needs only to add a slight excess of a barium salt in lieu of sulphuric acid. As regards phosphorus, there can be no doubt that its presence is objectionable, and it is correct to say it injuriously affects the quality of any kind of steel. Sulphur is not so injurious.

The use of the spectroscope for controlling the blow is practically condemned; the author's experience, however, is not in accordance with that of other metallurgists. The basic process is shortly noticed, and the basic reaction summarized in a few words.

The part played by manganese as a steel improver is thoroughly discussed, the various theories are well ventilated, and the great affinity of this metal for oxygen insisted upon and emphasized. Manganese, however, when alloyed with iron in small quantities, can scarcely improve the quality. Mr. Hadfield's new alloys of manganese and iron cannot strictly be termed steel; the alloy possesses some of the properties of steel, and it may be compared to brass, which is not copper, but is, nevertheless, a substitute for copper, as candidly acknowledged by the author. His views as regards the mischievous action of small quantities of manganese contained in steel cannot be accepted in their entirety: they are certainly contrary to results of every-day practice in Bessemer steel works.

A theory of steel may be accepted as it is written; there can be little doubt as to the existence of a definite carbide of iron which alloys with metallic iron; although we have the alternative of assuming that carbon is simply difficultly soluble in molten or highly heated iron, yet the evidence seems in favour of the existence of the carbide. The properties which distinguish steel from crude iron are marked.

Alluding to the use and value of spiegeleisen, the author, curiously enough, confirms the old, nearly forgotten theory of Mushet, *i.e.* that for the steel manufacture, the triple compound of iron, manganese, and carbon is absolutely necessary. The carbide of iron, Fe_4C, must be more fusible than metallic iron, and some acute observations are made on the part which this fusible compound plays in the heating and cooling of steel under varying conditions. In other words, it is probable that the properties of hardening and tempering are thus conferred on iron, for this compound must be in a semi-fluid or plastic condition, whilst the iron is comparatively infusible. As liquids in cooling contract to a greater extent than solids, it is easy to imagine variations in temper or hardness due to the more or less rapid cooling of the steel. Sudden cooling must produce a violent molecular tension by the resistance of the rigid iron to the greater contraction, and variations in cooling, greater or less, must produce corresponding differences in the hardening or temper of steel. It is noted that, as regards solids, the coefficient of expansion is less than that of liquids; also, that the more fusible solids have a higher coefficient of expansion than the less fusible. This also plays a part in the production of the final product; and steel may be termed a *heterogeneous solid*, not homogeneous as usually assumed. Sir Lowthian Bell and Prof. Abel, however, assert that on heating piles composed of alternate layers of steel and wrought iron, the carbon contained in the former slowly diffuses, and the iron absorbs carbon from the steel. It is, therefore, probable that the heterogeneous solid of the author must, after repeated heatings, become practically homogeneous, and it follows that the so-called carbide, Fe_4C, may thus suffer decomposition.

In conclusion, after discussing the properties of alloys, particularly the alloy of sulphur and phosphorus with iron, the author ventures to state a general law, that the hardness of an alloy does not depend on the mean hardness of its constituents, but is harder than either of them, quoting numerous instances in support of this law. It is difficult to gainsay all this, and we recommend the theory of steel to the careful consideration of metallurgists. Other theories may be broached; for instance, carbon may, as before said, be soluble with difficulty in iron, and the proportion left in solution may depend on the rate of cooling, a portion remaining insoluble, showing its presence in the form of graphite or simply intermixed carbon. Prof. Akerman holds that carbon exists in iron in three different forms which may be distinguished; other well-known metallurgists confirm his views.

The following chapters, on iron *versus* steel for structural uses, and the stability of iron, are apparently ably written, and are recommended for the consideration of experts. The article on occlusion of gases in iron and steel is up to date. The researches of Graham, Deville, and Troost are quoted, and prominently those of Dr. Muller, to which latter the author appears to attach some importance. Iron, however, occludes other elements just as it does hydrogen—such as zinc, cadmium, magnesium, &c.; the same may be said even of carbon during the cementation process. Dr. Muller's method of collecting the gas by drilling gives no information as regards the gas actually occluded, which latter, it is evident, can only be extracted by heating in vacuum, as recommended by Prof. Roberts-Austen, and practised by Graham and Troost, also recently worked by Parry, Stead, and other chemists. JOHN PARRY.

THE THEORY OF LIGHT.

The Theory of Light. By Thomas Preston. (London: Macmillan and Co., 1890.)

MR. PRESTON has written a valuable book on an important subject, one which will, as he hopes, be suited to the reading of junior students, and yet sufficiently full to meet the requirements of many who desire a more special acquaintance with the subject. At the same time it is difficult to avoid expressing the wish that he had carried the mathematical development of some parts of his subject a little further, and, if space required it, had omitted some of the more elementary details; though the work, within the limits laid down, is so well done, that criticism may seem ungenerous.

The historical method adopted in some parts of the book adds greatly to its interest, and the account given of the development of the subject, from the days of the Greek philosophers to the present time, will lead many to study the original sources of Mr. Preston's information with profit to themselves. It is a good thing for us to read how the first masters of the subject expressed themselves; to know what were the difficulties they felt, and what the problems which appeared important to their minds. We, who, thanks to Young and Fresnel, have had the difficulties that surrounded the wave theory in the time of Newton cleared away, are less apt than we might be at recognizing their magnitude, and at grasping the ingenuity and skill with which Newton treated the emission hypothesis, and the marvellous manner in which, in his hands, it was made to explain many of the phenomena of light.

In the earlier chapters of the book, after an explanation of the rectilinear propagation of light, a good deal of space is devoted to the explanation of phenomena usually dealt with under geometrical optics. The ordinary formulæ for prisms and lenses are deduced from the principle that the time from a point to its image is the same by all paths possible for the light—a principle which, in Lord Rayleigh's hands, has led to important results in the theory of optical instruments.

The argument given by Lord Rayleigh in his article in the "Encyclopædia Britannica," for showing that the effect of a wave is equivalent to half that of the first Huyghens zone, and that the phase of the disturbance is a quarter-period behind that from the pole, might with advantage have been given in greater fulness in Article 54 (the reference at the end of that article should be to Art. 154, Ex. 3).

The book is very complete so far as it goes, but the limits imposed by the author on himself do not allow him to show any very great originality in treating his subject, at least until we come to chapter ix., section iii., where he deals with the graphic method of solving problems in diffraction. In this section Cornu's beautiful method is employed, and many problems, usually only solved by analysis, are completely worked out by it.

The analytical solutions are, perhaps, a little hardly dealt with, as the methods of evaluating Fresnel's integrals given by himself, Gilbert, and Knochenhauer, only appear as examples. The theory of the diffraction gratings strikes us as being also rather brief. Rowland's concave gratings are best treated from the consideration that the waves from all the bright spaces arrive in the same phase. Possibly Bessel's functions are outside the limits of the mathematical treatment allowed by the author: if not, a reference to them would improve the treatment of the diffraction problems arising out of the case of a circular aperture.

Fresnel's theory of double refraction is given clearly in chapter xii., and the difficulties of finding a dynamical explanation of it are well stated. It is here, however, and in the chapter on the dynamical theory of reflection and refraction, that we think the limitation of the mathematical development unfortunate. The elementary theory of elastic solids is given sufficiently for optical purposes in several works accessible to students. The author might easily, if he had liked, have introduced a few pages of it in his own book. He would then have been able to give and discuss the theories of refraction and double refraction of both Green and Neumann, or McCullagh, and thus have added greatly to the value of the work.

The book is brought up to date in a satisfactory manner. The last chapter contains an account of the modern work on the electro-magnetic theory of light, including the recent experiments of Hertz.

ENGLISH PATENT LAW.

The Law and Practice of Letters Patent for Inventions; with the Patents Acts and Rules annotated, and the International Convention, a Full Collection of Statutes, Forms, and Precedents, and an Outline of Foreign and Colonial Patent Laws, &c. By Lewis Edmunds, D.Sc., (Lond.), F.C.S., F.G.S., of the Inner Temple, Esq., Barrister-at-Law; assisted by A. Wood Renton, M.A., LL.B., of Gray's Inn, Esq., Barrister-at-Law. (London: Stevens and Sons, Limited.)

THIS is a work of considerable pretensions. We see by his preface that Mr. Edmunds claims to have produced a comprehensive treatise, dealing exhaustively with Patent law and practice, and when we mention that the book runs, in this its first edition, to upwards of 900 pages, our readers may be disposed to think that the author must have achieved his purpose. On a closer inspection, however, the formidable proportions of the work become greatly diminished. We find that the actual text of the book is only some 425 pages, the remaining 515 pages being supplied by statutes, Patent rules, international regulations, voluminous forms, and an index. We have always understood that a legal text-book ought to be in form as concise, and we might almost say as condensed, as possible, consistently with the importance of the subject-matter. Mr. Edmunds does not appear, however, to pay much regard to this wholesome rule. We rarely remember to have seen a legal text-book more gratuitously padded out than the work now before us. To take one illustration, the author devotes nearly 200 pages to printing the Patent Acts 1883–1888, twice over, for what good purpose we are at a loss to understand. The notes which are appended to what we must, under the circumstances, call the first edition of the Patent Acts 1883–1888, are of considerable value, but we cannot approve the system of cross references, by means of which the author seeks to incorporate, under various sections of the Acts, passages from the preceding text. By this device, Mr. Edmunds seems to have attempted to combine in one volume two inconsistent methods of text writing—the method which constructs a book by noting the sections of an Act, and the method which, relegating the statutes to an appendix, makes the body of the text a continuous treatise. There is much to be said for each method. Mr. Lawson's admirable work on Patent practice is an excellent illustration of the first; and the now old but well-known work of Mr. Hindmarch on Letters Patent is a felicitous adoption of the second. But we do not think a cross between the two can ever be satisfactory. Considering how fully Mr. Lawson's work meets the needs of practice, and how much more convenient it is in point of size than the book now before us, we think Mr. Edmunds would have done better to have devoted himself to the production of a treatise on substantive law only. A new work on Patent practice was not required by the legal profession, but a new work on substantive Patent law has long been a public desideratum; and we think the present author, with his industry and evident ability, might well have supplied that want. We are afraid, however, that that want still remains to be supplied.

Coming to what is the text of the book—Part I., Patent Law and Practice—we notice that Mr. Edmunds gives in his first three chapters an interesting historical account of the origin of English Patent law. But we are disappointed to find that the very important question of subject-matter is but scantily treated in a chapter of thirty-four pages. This in a work of nearly 1000 pages, claiming to be an exhaustive treatise, is a surprising deficiency. In this part of his book, Mr. Edmunds has, in fact, limited his space far too much, and betrayed a tendency to huddle important cases into footnotes—a tendency the more to be regretted considering the size to which the book has otherwise been allowed to grow. In his chapters on specifications and infringement, the author has been much more successful, and these show great care and considerable merit. The chapters on foreign and colonial Patent laws are interesting, but necessarily short, and where a statement of law has to be so condensed its utility must be very doubtful. The table of cases is very complete, and it is a useful addition to the usual citations to add, as Mr. Edmunds has done, the dates of the decisions. The appendix of forms is a very full one, and the index seems to be well compiled. The immense increase in the number of patents granted by the Crown in recent years has given to this department of our law a greatly enhanced importance, and while we have not scrupled to point out what we regard as the defects of Mr. Edmunds's work, we doubt not that the book will have a large circulation amongst those whose professional duties lead them to consult works on this branch of English law.

OUR BOOK SHELF.

Lessons on Health. By Arthur Newsholme, M.D., D.Ph. (Univ. Lond.). (London: W. H. Allen and Co., 1890.)

UP to the year 1889, the Science and Art Department of South Kensington required that candidates for the examination in hygiene should at some previous time have passed the Departmental test in physiology. Since that date, however, the Science and Art authorities have decided that the hygiene paper shall contain questions on physiology, embracing the general structure of the human body, the forms, positions, and uses of the more important organs, more especially the construction and action of the circulatory and respiratory systems, and of the digestive and excretory organs; and that a separate examination in this subject shall be dispensed with. Dr. Newsholme's "Lessons on Health" is a manual designed to cover the requirements of the elementary stage of the hygiene examination under the altered regulations. Writing for elementary readers, the author wisely begins by devoting a chapter to the chemistry of the chief elements which enter into the composition of the body. The next four chapters are taken up with histology and physiology, but here we do not think the author has entered sufficiently into detail to enable beginners to grasp the full meaning of what they are reading. Our objections have special reference to the histology. For example, the author tells us that the tissues, when examined microscopically, are found to consist of cells, which, in the case of muscular and connective tissues, have become transformed into fibres; and that the original appearance of cells is best seen in the cells of connective tissue, brain, and epithelium. No explanation, however, is given as to what is meant by a cell; nor even a brief account of the appearances and structure of the other tissues of the body; so that, when the reader comes to learn such facts as that the stomach is composed of four different coats, or that there are three layers in the wall of an artery, the latter differing from a vein in possessing more elastic tissue, he cannot form any adequate idea as to the meaning of these words. Again, in the description of the skeleton, the sterno-clavicular articulation is mentioned, but no allusion is made to the joint between the clavicle and scapula; the ulna is said to articulate with the humerus, but no mention is made of the fact that the head of the radius enjoys the same privilege.

The matter in the hygiene section of the book, both in arrangement and description, is excellent, and may be cordially recommended for the purpose intended.

J. H. E. BROCK.

Practical Inorganic Chemistry. By E. J. Cox, F.C.S. (London: Percival and Co., 1890.)

THIS is a volume of 51 pages, consisting of "the necessary notes, reactions, and analytical tables constantly required for reference" by students preparing for the elementary stage examination of the Department of Science and Art in practical inorganic chemistry. As only seven bases and four acids are included in the syllabus, and the mixtures given are soluble in water or dilute acids, the scope of the volume is very limited. The author begins by stating the possible number and character of the constituents of mixtures that come within the range of the syllabus, and then gives a list of all the substances available for the examiners to make the mixtures from. Then follow lists of reactions and tables of methods. After these is a quotation from the published description of that part of the examination that consists of questions to be answered, and as the examiners state that "the value of the answers will be greatly enhanced by neatness and clearness of sketches," the author proceeds to give "the sketches required," a series of 21 figures all duly labelled, and which presumably includes every sketch that can possibly be needed. The student is recommended to practice copying the figures until he "can draw the apparatus neatly and accurately."

Notes on Trigonometry and Logarithms. By Rev. J. M. Eustace, M.A. (London: Longmans, Green, and Co., 1890.)

THIS work is not like an an ordinary text-book, but consists of a series of well-arranged notes on the elements of trigonometry and logarithms. The subject is treated so that it may be useful to beginners, and to those working it up by themselves. The book-work will be found fully worked out, and, in each chapter, examples on it are given to demonstrate the methods of solution.

Great care has been bestowed on the explanations of the various manipulations to which logarithms can be applied, and the author has reprinted some pages of the mathematical tables published by Messrs. W. and R. Chambers, giving a full explanatory account of the method of using them, which to a beginner will prove most serviceable. Two excellent chapters on solutions of triangles and heights and distances give the student a good insight into the more common problems that are generally worked out in this way.

Miscellaneous propositions and examples are dealt with in the last two chapters: in the former, such propositions as the nine-point circle, distance between centres of circumscribed and escribed circles of triangles, &c., are discussed; while in the latter we have a series of well-selected examples taken from the usual sources.

Elementary Statics. By the Rev. J. B. Lock, M.A. (London: Macmillan and Co., 1890.)

MANY are the treatises which deal with the subject of elementary statics, but few can rival in clearness the present stereotyped edition of Mr. Lock's work. The alterations that have been made have not necessitated any considerable change in the character of the book. By the addition of some fully worked out illustrated problems, and of a carefully graduated set of interesting examples for the student to solve, the author has slightly enlarged the scope of the treatise. The number of the miscellaneous examples at the end have been greatly increased by the insertion of problems that have appeared in the Cambridge examinations in the last two or three years. The subject throughout is treated in the author's best style, and the book can be cordially recommended for the use of beginners.

Die photographische Retouche in ihrem ganzen Umfange. By Wilh. Kopske. (Berlin: Robert Oppenheim. 1890.)

IN order to remove the defects incidental to photographic pictures, a process of "touching up" has to be resorted to, and the present pamphlet of 80 pages in length offers instructions in this subject, which will be found of use by practical photographers. The amount of valuable information compressed within the compass of the little work before us is quite remarkable, and shows that the author is thoroughly familiar with this branch of his art. We can commend the book to photographic artists.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Photographs of Meteorological Phenomena.

AT the Leeds meeting of the British Association a Committee, consisting of Mr. G. J. Symons, F.R.S. (Chairman), Prof. Raphael Meldola, F.R.S., Mr. John Hopkinson, and myself, was appointed to report upon the application of photography to the elucidation of meteorological phenomena, and to collect and register photographs of such phenomena.

The success with which these instructions can be carried out necessarily depends in a great measure upon the voluntary co-operation of others.

Will you therefore allow us to appeal to photographers through the medium of your columns, and to ask all those who have in their possession negatives of clouds, lightning, hoar-frost, hailstones, or any other meteorological phenomena, or of damage done by whirlwinds, tornadoes, or storms, to communicate with me?

We shall be grateful for copies of any such photographs, but shall especially welcome offers of future assistance in the shape of photographs taken in accordance with some simple instructions which will be supplied on application.

ARTHUR W. CLAYDEN.

Warleigh, Tulse Hill Park, London, S.W., November 18.

Some Habits of the Spider.

THE experiment given by Mr. Boys can be successfully made with a common table-fork. The spider will seize the handle and grapple with it in a ridiculous fashion, but it soon tires of the performance. The prongs will continue vibrating for some little time if struck smartly on a wall.

A curious habit of the spider has perhaps been recorded, but I have never seen it noted. A large, dark spider is sometimes seen in the centre of a strong and regular web. Blow the spider with a slight puff, and if it does not fall or run away, it will shake itself violently for a quarter of a minute. These oscillations are not natural, as the spider will only produce them once or twice, and the natural oscillations are slower. The motion is circular and very rapid, so that the outline of the spider disappears and a blurred appearance three or four times as large as the spider is produced.

This habit is probably protective. Birds would be puzzled rather than frightened, and would find it difficult to make a good shot at the spider. The species of spider is fairly common in gardens and hedges, and is abundant in parts of Norway. It is dark, with a few light spots.

Newton's Rings.

WHILE arranging some experiments on the interference of light for class illustration at the Working Men's College, Melbourne, with a friend, Mr. Wilfred Kernot, of this city, we came across a method of showing Newton's Rings which I have not seen described, and which may be new to some of your readers, though probably any who have had to arrange the experiments for themselves will have come across it.

The apparatus used was a pair of glass plates, $2\frac{1}{2}$ inches square by $\frac{3}{16}$ inch thick, squeezed by a pair of clamps at the centres of a pair of opposite edges. A beam from an electric lamp (900 candle-power) was sent through the plates so as to be partly reflected and partly transmitted, and the images formed by these two beams were received on a pair of screens about 5 feet from the plates. Holding the plates at an angle of about 10° with the incident beam, the complementary colours are shown with great brilliancy on the screens; by varying the inclination of the plates to the beam the colours can be changed at pleasure.

In this form the experiment is well suited for class illustration; care is necessary to avoid irregular reflection at the edges of the plates; we covered ours with ordinary gum paper.

B. A. Smith.

Working Men's College, Melbourne, October 10.

Mutual Aid among Animals.

Recent discussion of this subject has recalled my attention to an observation made some time ago, while studying the animals of Casco Bay, on the coast of Maine.

Among the specimens brought back from one excursion were four of the common Echini (*E. drobachiensis*). The last one taken had been left exposed to the sun some time before it was noticed and properly cared for.

These four animals were placed alone in a small aquarium, and, as we wished to study the action of the ambulacræ, each was turned mouth up. Soon the action began, with which every naturalist is familiar, and three of the captives slowly rose on edge, and then deliberately lowered themselves into the normal position. The fourth, the injured one, made much less rapid progress: all it could achieve was a slight tipping of its disk. The two nearest Echini, from six to eight inches distant, now moved up and stationed themselves on opposite sides of their disabled comrade.

Fastening their tentacles for a pull, they steadily raised the helpless urchin in the direction in which it had started. As soon as it was possible, one of the helpers moved underneath the edge of the disk on the aboral side, and, when the half-turn was accomplished, the other took station on the oral side, gradually moving back as the object of so much solicitude was very gently lowered to the position nature had made most convenient.

This is the best instance of "giving a lift" I have ever met with among animals of so low a grade. It may not be without interest to others.

Colby University, Waterville, Maine, U.S.A.

The Chrysanthemum.

This being the centenary year of the introduction of the Chrysanthemum into England, a word on the subject from its native place, Peking, may not be out of place. It is not generally known that the Chinese grow the Chrysanthemum as a standard tree especially for selling. They graft them on to a stalk of Artemisia. There is a species of Artemisia that grows wild and covers the waste ground round Pekin; it springs from seed every year, and by the autumn attains to a tree 8 or 10 feet high with a stem 1½ inch thick. The Chinese cut it down, and, after drying it, use it as fuel; the small twigs and seeds are twisted into a rope, which is lighted and hung up in a room to smoulder for hours; the pungent smell of the smoke drives out the mosquitoes. This plant, after being potted, is cut down to about 3 feet and used as the stock, the twigs of Chrysanthemum are grafted round the top, and it quickly makes a fine tree, the flowers grow and open, and as the stock soon withers the whole tree dies, and folks say, "another ingenious fraud of the Chinamen."

A favourite style of growing Chrysanthemums is in the shape of a fan, with eight or ten flowers in different parts of it. If the flowers are not grown on the plant, they are tied on, which also does for selling.

The winters in Peking are very cold, and last about four months, and having no glass houses the Chinese gardeners do not have the chance of producing such a variety or such fine flowers as their European brethren, but in the case of Chrysanthemums they have many curious and beautiful varieties.

Thos. Child.

Dispersal of Freshwater Shells.

I am putting together such instances as I can find of dispersal of freshwater bivalves by closure of their shells so as to cling to the toes of birds, amphibia, water-beetles, &c., and of univalves by adhesion to the wing-cases of water-beetles, &c., and venture to ask for co-operation. Any notes or references which your readers may have the kindness to send to the undermentioned address will be welcomed and carefully acknowledged.

H. Wallis Kew.

The Common Sole.

The post-larval flat-fish obtained in 80 fathoms off the west of Ireland, which in Nature (vol. xlii. p. 520) I referred to as common sole, have turned out, on closer examination to be the fry of *Pleuronectes cynoglossus*, called "white sole" in the Dublin markets.

I shall feel obliged by your finding space for this correction.

Dublin, November 15. W. Spotswood Green.

The Scientific Investigations of the Fishery Board for Scotland.

In the review of the "Eighth Report of the Fishery Board for Scotland," which appeared in Nature (vol. xlii. p. 653), the reviewer, misled by the private information to which he refers, makes an inaccurate and baseless statement, reflecting upon me personally, and which I therefore crave leave at once to correct. In dealing with my report on immature fish, which, by the courtesy of the Secretary for Scotland, was placed in the hands of the delegates of the recent International Fisheries Conference, and which has already been referred to in your columns by Prof. McIntosh, F.R.S., the reviewer states: "We have certain information that the *original discoveries which led to* this report were made" by Mr. T. Scott; and that "it is only fair that the credit which is Mr. T. Scott's due, *and which is denied him there*, should be acknowledged here."

Had your reviewer disregarded his private information, and looked at p. 161 of the paper which he has reviewed, he would have found there the following footnote to the statement that "nearly 13,000 food-fishes" had been "carefully measured, and the condition of the reproductive organ registered," viz., "*This has been mainly done by Mr. Thomas Scott, F.L.S., one of the naturalists of the Fishery Board, and partly by Mr. Peter Jamieson, assistant naturalist.*"

What Mr. Scott and Mr. Jamieson did was precisely what is stated—namely, to measure the length of the fish and record on the form provided whether the milt or roe was mature or not. The subjoined note from Mr. Thomas Scott, which I request you to publish along with this, shows that he considers this acknowledgment sufficient. The study and elaboration of these daily records, nearly 13,000 in number, mainly in my private time, was only a part, and a small part, of many months of labour bestowed on my report on immature fish; and the results occupy less than three pages of the fifty-four devoted to the subject. No other person had any part or share whatever in the conception or composition of that report, and this attempt to deprive me of the credit of my work, solely on the strength of private and erroneous information, is not, I think, either usual or creditable.

The reviewer is equally in error as to what I wrote in the Report for 1887, and which he only partially quotes. The entire sentence is as follows: "We have organized a series of extensive and systematic inquiries into the condition of the reproductive organs of the various kinds of fish throughout the year, with particulars as to their sizes, the nature of their food, &c., which will help to clear up the hitherto obscure problems as to the minimum size of sexually mature individuals, the commencement and duration of the reproductive period, the spawning places, and many other points of great interest." If the reviewer will now peruse p. 8 of the Seventh Report, he will find it there stated that these inquiries were "*devised by Dr. Wemyss Fulton*" (in 1887), which is the fact.

T. Wemyss Fulton.

20 Royal Crescent, Edinburgh, November 3.

14 *Lorne Street, Leith, November* 1.

Dear Sir,—I have read the article in Nature of October 30, and desire to say that I consider the footnote at p. 161 of part iii. of the Board's Report for 1889 a sufficient acknowledgment of my work in connection with the immature fish investigation.

You have always from the first acted towards me in a very friendly manner, and would be the last to detract from any credit belonging to me.

Thomas Scott.

Dr. T. Wemyss Fulton, Secretary Scientific Investigations.

Araucaria Cones.

Having been away from home, I have only now seen the Duke of Argyll's letter in Nature of November 6 (p. 8), relating to the cones of Araucaria. Doubtless before this some of your correspondents have answered the Duke's inquiry.

It is not very unusual for the *Araucaria imbricata* to produce cones. The first I myself remember to have seen were on the old tree in the Royal Gardens, Kew, in the summer of 1851 or thereabouts. The female cones are large globular masses, the constituent scales of which are not (superficially) very different from the ordinary leaves. What the Duke describes are evidently the male catkins. The trees are ordinarily diœcious, but I have once seen and figured an example in which male catkins and female cones were borne on the same tree.

London, November 14. MAXWELL T. MASTERS.

IN the garden of the house Bleckley, Shirley Warren, Southampton, there is an Araucaria that for many years past has produced annually a large number of cones. The cones are from 40 to 100 in number, and very large, so that their breaking up and falling on to the lawn is a serious inconvenience, it being difficult to sweep them up. No fertile seeds have been produced by this tree, which from all I have been able to learn is the finest Araucaria in England; the trunk is over 6 feet in circumference some 2 feet above the ground. There is no history of the tree.

Cambridge, November 15. D. SHARP.

IF the Duke of Argyll refers (November 6, p. 8) to ovule-bearing cones, which are spherical and about 7 inches in diameter, these have been plentifully produced in almost every part of the British Isles.

Male or pollen cones (catkins), of cylindrical shape and 3 inches long, are, however, extremely rare, although they have been produced in the Bicton Pinetum and on one of Earl Derby's Kentish properties. A tree at the latter place bears annually, and has done so for some years, a heavy crop of perfectly-developed pollen cones; indeed, so great is the quantity that at a short distance away the tree has quite an unusual and remarkable appearance. A. D. WEBSTER.

Holwood Estate, Kent, November 17.

ATTRACTIVE CHARACTERS IN FUNGI.

THIS subject, which has been introduced by a letter from a correspondent (November 6, p. 9), is one of considerable interest, but it is one also of great mystery and difficulty. In dealing with fungi of the mushroom type we are in contact with a class of plants so different from Phanerogams that it is at once evident that we must not draw the same conclusions from a similar series of initial facts. It is well known that certain fungi possess strong and characteristic odours, and others very conspicuous colours, both of which features are presumed to have some value in the biography of the plant, but *what* influence and *what* value it is not so easy to determine as in the case of plants in which cross-fertilization has to be effected. It is by no means certain that there is any special act of fertilization at all; it is even doubtful if any fertilizing element exists. For nearly a century it has been thought possible to find a fecundating element in Agarics, but all efforts at demonstration have failed.[1] Most of these investigations have been directed to the cystidia, large cells which are recognized as projecting, more or less, on the surface of the hymenium, but these could not be identified with any known process of fecundation.[2] M. de Seynes, after patiently investigating the hymenium of the *Hymenomycetes*, arrived at a negative result, and this has not since been disturbed. "The hymenium," he says, "has not yet offered an organ which we may suppose in reality to be the male organ;" and he adds, "one sole and self-same organ is the basis of it, according as it experiences an arrest of its development; as it grows and fructifies, or as it becomes hypertrophied, it gives us a paraphysis, a basidium, or a cystidium; in other terms, atrophied basidium, normal basidium, hypertrophied basidium: these are the three elements which form the hymenium. Does it develop either outside the hymenium or on the hymenium, at a time, or in a part which has not yet been discovered, organs which yield pollen, spermatia, antherozoids, or any other fecundating agent? This is what remains to be discovered."[1]

[1] De Bary, "Morphologie und Physiologie der Pilze," cap. v.
[2] See *Grevillea*, vol. i. (1873), p. 181.

Amongst British mycologists Mr. Worthington Smith has been the most persistent in belief that Agarics are subject to hybridism, which implies cross-fertilization, but he has not contributed much towards the establishment of the proposition that fertilization really exists, except perhaps to emphasize the suggestion that the cystidia are male organs. In his paper on the reproduction in *Coprinus radiatus*,[2] he remarks: "I consider it quite possible that the mere contact of the threads (or fluid) from the cystidia with the threads from the unpierced spores may be sufficient for the production of a new plant." In more direct reference to the question of hybridism he writes:—"On a dung-heap, which will produce *Coprinus radiatus*, other species, as *C. nycthemerus*, &c., are sure to appear; and not only do allied species come up in company with *C. radiatus*, but every intermediate form between one and the other may be gathered any morning. These latter plants belong to no species described as such, but are natural hybrids, doubtlessly produced by the spermatozoids of one plant piercing the spores of another. Amongst the larger species of Agarics similar forms are quite common, and they prove sore puzzles for those men who only want *names* for the fungi they find."

No one with any extended experience in field work can gainsay that individual Agarics are often met with which strongly suggest hybridism. These forms are so intermediate between more typical forms, with which they were perhaps growing, that it is difficult to get rid of the idea altogether that they are modifications due to some such influences as in higher plants we attribute to hybridization. It would be very unphilosophical to deny absolutely that they are possibly hybrids; but, on the other hand, it would be as bad to declare them hybrids until some sort of impregnation can be demonstrated.

Admitting that hitherto all efforts to discover any process of fertilization in Agarics, which will stand the test of examination, has failed, the difficulty is increased in speculating upon the "why and wherefore" of the phenomena of odour, taste, and colour, in the larger fungi. Yet, notwithstanding this, we may approach nearer the desired end by endeavouring to collect facts, which may some day, by accumulation, serve as a basis for hypothesis.

Why do certain fungi possess very strong odours, which to our olfactory nerves are agreeable or disagreeable? There is a small whitish Agaric, not uncommon amongst grass in woods, which has such a strong and peculiar odour that it is named *Agaricus* (*Clitocybe*) *fragrans*. It is not more than about an inch in diameter, is mild to the taste, very pleasant to eat when cooked, and the odour remains after the plant has been dried for some time. Some persons detect in it a resemblance to anise, others to melilot, or the Tonquin bean, and others again regard it as an odour peculiarly its own. Two or three other species, to be found in similar localities, might, at a glance, be confounded with it, but that they are destitute of the odour and pleasant flavour. The novice could at once distinguish this fungus from its associates by its odour, but wherefore it should smell so sweet whilst the others do not is at present an unsolved mystery. It is certainly not specially attractive to insects, and we have never found it attacked by slugs; perhaps the odour is disagreeable to them.

Another Agaric may be found amongst dead leaves, which is twice as large, and of a singular pale verdigris-green colour (*Agaricus* (*Clitocybe*) *odorus*). It possesses very nearly the same odour, possibly a little stronger, and the same agreeable taste. This, again, we have always observed to be free from any indication of attacks from slugs. We have failed to detect the same odour, except

[1] *Grevillea*, vol. ii. p. 41.
[2] *Grevillea*, vol. iv. (1875), p. 53.

perhaps very faintly in one or two instances, in any other species of Agaric. There is, however, a *Lactarius* which resembles an Agaric in form, but contains a copious supply of white milk somewhat acrid to the taste, and an odour not much unlike but rather more camphoraceous than the two Agarics. This is *Lactarius glyciosmus*, which has a reddish-cream colour when dry, but is more ruddy when moist. In addition we may mention a densely tufted fungus growing on stumps, *Lentinus cochleatus*, with a fainter but similar odour to the *Agaricus odorus*. One species of *Hydnum*, in which the gills of the hymenium are replaced by spines, has but a faint smell of melilot when fresh, but in drying this odour is intensified, and remains persistent for three or four years. This is known as *Hydnum graveolens*, but is somewhat rare in Britain. Finally, we have two species of woody *Trametes*, found growing on trees, which possess an odour of the same type. These are *Trametes suaveolens* and *Trametes odora*, and quite resembling them is *Trametes inodora*, which has no distinct odour at all. The chemical character of this odour has never, to our knowledge, been investigated, but the point now in question is the reason for its existence, and for this all conjectures hitherto offered are weak. In several of the fragrant species it will be remembered that there are similar and allied species which have no perceptible odour; it is possible that this fact may have some value in the investigation.

Passing over other types of odour which prevail in fungi, we will take as a final example a pungent odour as of nitric acid, which is by no means uncommon. It is rather rare with white-spored Agarics, but is often met with in pink-spored species, many of which are either doubtful or poisonous. The majority of instances amongst white-spored species will be found in the subgenus *Mycena*, wherein the species are small and delicate, such as *Agaricus* (*Mycena*) *alcalinus*, and *Agaricus* (*Mycena*) *ammoniacus*, to which may be added also *Agaricus* (*Mycena*) *metatus* and *Agaricus* (*Mycena*) *leptocephalus*, although in a less degree; but the culminating examples will be found in the *Hyporrhodii*. One of the commonest of woodland Agarics in the autumn is *Agaricus* (*Entoloma*) *nidorosus*, which the nose will always determine if the eyes should fail. It is a pale mouse-coloured species, generally about 2 or 3 inches in diameter, which the odour would be sufficient to deter anyone from feeling desirous of tasting, if it had not also a very suspicious appearance. It may be taken for granted that where this odour prevails the species are not edible, even should they escape being positively poisonous. There is a suggestion of the same odour in *Agaricus* (*Hebeloma*) *elatus*, but a full development of it in *Agaricus* (*Hebeloma*) *nauseosus*. It becomes faint in *Agaricus* (*Pholiota*) *heteroclitus*, as it is also in *Cortinarius nitrosus*; but in all there is more or less of the same pungency, which recalls to mind the fumes of nitric acid. It may be inferred from the name of *Hygrophorus nitratus* that it possesses the same odour, and others might be named which partake of it in a less degree, so that this may be accepted as another type of odour to be found in many species of fungi. Here, again, the same question arises as to what value this peculiarity may be supposed to possess for the plant itself, because it is no symptom of decay, since it is present with the plants named above in their youngest and in their most healthy condition. Nothing that we have observed would suggest protection from, or attraction for, insects or mollusks.

Thus much for odours, which must be taken as suggestive, and not by any means exhaustive. The subject of taste may be passed over as of doubtful value in estimating attraction or repulsion, or at least it is of secondary importance, and should not stand in the way of a few suggestions on the subject of colour. It may be premised that, although such a large number of species of Agarics flourish amongst grass, very few possess a green colour. We have alluded to one which is most commonly found amongst dead leaves; *Russula virescens* is seldom seen amongst grass, and the colour of *Agaricus æruginosus* is not in the least concealed when growing amongst grass, until it has lost the greater part of its green gluten and exhibits the dirty yellow cuticle. Dull-coloured species, of various shades of olive, brown, and grey, are common enough, so as readily to be confounded with the soil, stones, and dead leaves, upon or amongst which they are growing; but what excuse can be made for the bright red and yellow species appearing in such gaudy attire? Reds verging upon deep orange, as in *Agaricus* (*Amanita*) *muscarius*, and passing through all stages of vermilion and carmine to deep purple, are by no means uncommon, especially in the genus *Russula*. And here it may be remarked that the species of *Russula* are to be seen in greatest plenty and perfection during those months when flowers are exhibiting their brightest colours, and before the mass of proper Agarics make an appearance. A red *Russula* in October or November would be a far more conspicuous object than if it occurred in June or July, when *Russula* puts in an appearance. *Hygrophorus*, on the other hand, is a late genus, containing some very bright red and yellow species; but these are small, and commonly so immersed in the grass, on lawns and pastures, that they are not conspicuous. Their "season" is October and November. It is easy enough to comprehend the advantage of coloration to such species as *Hygrophorus psittacinus*, *Hygrophorus conicus*, *Hygrophorus Wynniæ*, and even of *Hygrophorus chlorophanus*, when seen growing amongst autumnal grass. The large species of *Russulæ* would, under the same conditions, be most conspicuous. Out of forty British species there are not less than twenty-five which are of some tint of red, or have varieties of those colours. What protective value can there be in expanded disks of bright scarlet 4 or 5 inches in diameter? If it should be contended that they are attractive, and not protective, then it becomes a question as to what they may attract. Slugs are fond enough of devouring not only red, but white and dull-coloured species, not refusing a meal upon one of the most poisonous (*Russula emetica*), and still it is the top of the pileus they devour, apparently in preference to the gills, so that they cannot be regarded as intelligent workers in the distribution of species.

A careful examination of the plates in any good illustrated work on the Agarics will show that in the whole of the old genus *Agaricus*, adding also *Coprinus* and *Marasmius*, the number of brightly coloured species are remarkably few. In the genus *Cortinarius* the colours are brighter, but they are not conspicuous when growing, because violet is not a demonstrative colour, and pale yellow, or lemon colour, is not observable amongst dead leaves. If space permitted it could be shown that, in a majority of instances, the colours of Agarics are protective, inasmuch as they harmonize remarkably with the matrix that supports them. With *Russula*, *Lactarius*, and *Hygrophorus*, the case is different, for there are many very obtrusive species, notably the red ones, for which we cannot formulate an excuse.

A word or two, in conclusion, on the intermediaries, or agencies, for the diffusion of fungi. It must be understood that in this communication we are confining ourselves to the large, or pileate, fungi, principally of the mushroom type. The agents named in the letter already alluded to are: "Horses, oxen, sheep, foxes, squirrels, moles, birds, snails, and insects." Squirrels are very fond of *Boleti* especially, but they eat the top of the pileus in preference to the pores, or spore-bearing surface; snails and slugs are undoubtedly mycophagous to a considerable extent. Of birds we have no evidence, as far as I am aware; ducks will eat fragments, when thrown to them, of such known virulence as *Agaricus muscarius*, and *Boletus luridus* without subsequent inconvenience, but it is doubtful if birds seek fungi, except to beat them in pieces and pick out the larvæ. Whether horses, oxen, and sheep really *eat* the common mushroom, we venture to call in question, but they *do* eat the grass upon which fungus spores have fallen. We have observed horses, cattle, and sheep eating the grass all around where mushrooms have been growing, and seen them pass on, leaving the mushrooms for us to gather on our own account. This does not show much animal predilection for fungus food, and hardly bears out the paragraph that "horses, sheep, and oxen are all readily attracted by the taste and mealy smell" of the mushroom. Without venturing to throw doubt upon the old faith that the spores of the mushroom are doomed to pass through the entrails of a horse, or that a horse or cow may sometimes even eat a mushroom if one comes in its way, still we have great hesitation in accepting as an article of belief that horses are really so fond of fungi that they seek them out, and devour them bodily, for the sake of the preservation of the species. Mushroom gatherers by preference go into meadows and pastures where horses and cattle are feeding in order to fill their baskets, but this could hardly be the case if the animals themselves were so fond of the delicacy, and hence it may be inferred that it is not wholly true that mushroom spores pass through their host because that host recognizes the mealy smell and pleasant taste of the mushroom itself, but rather that they are swallowed unwittingly with the grass over which they are dispersed.

The general question still remains unanswered: "What can be the service which the presumably attractive characters of fungi induce animals to perform for them?" In the case of the *Phalloideæ* there need be little hesitation in furnishing an answer. The fœtid odour of *Phallus*, *Clathrus*, and their allies, undoubtedly attracts flies in great number, and these latter suck up the slimy mass, which contains the spores, with such avidity that scarce a speck is left. These spores are all most remarkably small,[1] so as to leave no doubt as to their being ingested whole, and probably excreted in the same condition, but how, when, and where, is a mystery still. The inference would be that, if true in this instance, why not similarly in others? and hence the inquiry. Unfortunately the data are too few for generalization, and all we can do is to demonstrate that the subject is worthy of investigation, and, as Mr. Straton has observed, "one that requires the gathering together of much individual observation in all parts of the world." Few people hitherto have considered fungi of sufficient interest or importance for any other effort than to kick them over whenever encountered, but in this respect a reform would be imminent, if, by reiteration of the questions here set down, and a wider distribution of suggestions as to the kind of observations required, a larger number of persons could be interested in looking for and recording them. If there are no sexual elements to be discovered, it is still desirable to ascertain what conditions are requisite to secure the successful germination and growth of the agamospores, and how intervening agents might aid the process. The least glimmer of light is always welcome in a dark place.

M. C. COOKE.

LUMINOUS CLOUDS.

LUMINOUS clouds, which were first seen in 1885, are now acknowledged to have so much importance that it may be worth while to present a brief survey of the phenomenon and the facts established by the observation of it.

On June 23, 1885, about 9.50 p.m., local time, I noticed an extraordinary brilliance produced by light-clouds in the north-western sky. I had always previously directed great attention to clouds, and on this account these bright clouds appeared to me the more surprising and puzzling. About 9.50 p.m. the north-western and northern sky was covered, to the height of about 20°, with a layer of bright cirrus-like clouds, which reached from about N.W. to N.N.E. In this layer, the lowest part of which was concealed from me by houses and trees, three horizontal zones could be distinguished. The lower zone was without lustre, and had a yellowish appearance; higher up there was a strip, several degrees in breadth, which shone with an extremely beautiful, white-gleaming, silver-like light; above this strip was another like it, but not quite so brilliant, of a bluish tint. The light of the central zone was comparable to the light of the nearly full moon, when it stands at sunset at about 10°, more over the eastern horizon. About 10.30 p.m. the height of the upper limit of the phenomenon had been somewhat lowered; the three zones were still there, but had become —especially the uppermost one—somewhat narrower.

The position of my place of observation—Steglitz, near Berlin—is 52°·5 N. lat.; about 9.50 p.m., local time, the depth of the sun below the horizon was about 9°. It is well known that, at this depth of the sun, ordinary clouds cannot any longer be affected by direct sunlight.

The same phenomenon appeared pretty often in the course of the following weeks; and I had, therefore, repeated opportunities of studying its peculiarities. I have never seen anything of the same kind at the time of sunset. As a rule, the phenomenon began to appear from 15 to 20 minutes—but sometimes 40 minutes, or more—*after* sunset. Several times I remarked that almost the whole sky—with the exception of a segment in S.E. at the height of from 10° to 20°—was covered by the gradually increasing brilliance. In all these cases a gradual, progressive extinction of the phenomenon, proceeding from S.E. to N.W., was observed. The luminous clouds, when they first shone, generally gave forth only a feeble light. As the sun sank deeper, a gradual, but in the end complete, extinction of the phenomenon took place from the south-eastern side; but at the same time the light of the remaining part became steadily stronger, until it reached its highest degree of strength, when the upper limit in the N.W. had a height of about 12°. From that point onwards the strength of the light decreased.

On some evenings the phenomenon was specially striking, less in consequence of the light than in consequence of an occasional want of light. Several times I observed—the sky having been perfectly clear when the sun set—that about an hour after sunset an absolutely impenetrable black wall, like a threatening thunder-cloud, appeared in the N.W., from the horizon to a height of from 5° to 20°. Higher up, on the contrary, the silver-bright shining showed the presence of the phenomenon. Gradually the black shadow disappeared, from above downwards, and gave place to the intense shining.

Towards the end of the month of July 1885 the luminous clouds disappeared, and it seemed as if the phenomenon had come to an end. It was therefore the more surprising when, towards the end of May 1886, the phenomenon again presented itself suddenly. As in the preceding year, it remained visible, with some interruptions, until the beginning of August. The phenomenon has since been repeated from year to year, always at the same season.

As the result of incessant efforts, I have succeeded in establishing that luminous clouds migrate in the atmosphere of the earth in such a way that during the months of December and January they are to be found in the southern hemisphere at the latitude of from about 48° to 60°. No information with regard to the phenomenon in equatorial regions has yet been received. This suggests the possibility that in passing through these regions it is not visible; but when we consider that also in the temperate zone there are extensive districts in which

[1] Not more than 3 micromillimetres in diameter.

the phenomenon must certainly have presented itself, but from which no record of observations has hitherto come, the fact that it has not yet been observed at the equator will not lead us to conclude that it is not visible there in intermediate times.

The above-mentioned decrease of the apparent height of the upper limit of the phenomenon, coinciding with the deeper sinking of the sun, causes us to recognize that it is due mainly to direct illumination by the sun. Starting from this assumption, we may readily find the principles for the determination of the height of the phenomenon. During the first years, therefore, I frequently made measurements of the apparent height of the loftiest point of the arc which limits the phenomenon towards the S.E.; and, having regard to the time of the measurements, I found that the distance of the phenomenon from the surface of the earth was from about 50 to 60 kilometres.

The knowledge of this extraordinary height excited in me the most intense interest, and my aim now was to determine the height by a more trustworthy method. For the ultimate success of my efforts I am especially indebted to the co-operation of Prof. Förster, Director of the Berlin Observatory. On the evening of July 6, 1887, Dr. Stolze and myself (the former having taken up his position in Berlin, while I observed the phenomenon from the Potsdam Observatory) succeeded in each getting two simultaneous photographs of the luminous clouds. The calculation made in accordance with these photographs gave a height of about 75 kilometres. But this estimate was not perfectly satisfactory, so far as precision was concerned; for, in the first place, the basis of about 26 kilometres was small; secondly, the direction of the basis was such that it formed with the direction towards the luminous clouds too small an angle; and, thirdly, the photographic apparatus employed had not been worked with sufficient exactness.

FIG. 1.

In the year 1889 the luminous clouds were at last repeatedly and simultaneously photographed, with improved apparatus, at Steglitz and Nauen, which are distant from one another about 35 kilometres, and lie with regard to one another in the direction from east to west. At Rathenow also, 70 kilometres west from Steglitz, photographs were taken. These were not exactly simultaneous with the others, but the time differed only by a few seconds; and they are useful at least as a means of checking the results obtained from the photographs taken at Steglitz and Nauen.

From these photographs it is inferred with great certainty that the distance of the luminous clouds from the surface of the earth on July 2, 1889, was 81 kilometres, and that it was 82 kilometres on July 31, 1889. For June 12 there is an estimate of 90 kilometres, but this is less certain than the other two.

These results follow from the measurement of 108 different points, corresponding to one another, which are distributed on six pairs of plates; and it is interesting, from the remaining errors of the single groups, to test more closely the question what part is taken in these errors by, say, the thickness of the cloud-layer in a vertical direction.

It is well known that there is a certain law relating to the probability of the distribution of errors in accordance with their greatness. According to this law, it is to be anticipated that errors which lie between the triple and the quadruple value of the mean error, occur *once* among 80 different points which have been measured in the photographs of July 2 (in which the conditions of accuracy were the most favourable); and, further, that of errors which lie between the double and the triple value of the mean error *six* are to be expected. In reality, the calculations agreed very well with the number of observed cases—viz. 2 and 5 respectively.

These figures show very plainly that the differences of the results with regard to the height are essentially a consequence of errors of measurement, and that the thickness of the cloud-layer itself was very small, perhaps only the fraction of a kilometre. With this agrees the almost exactly similar aspect of the phenomenon at the two places of observation.

Figs. 1 and 2 represent the phenomenon as it appeared on July 2, 1889. The photograph reproduced in Fig. 1 was taken in Steglitz at 13h. 21m. os., Berlin mean time, and Fig. 2 simultaneously at Nauen. It is interesting to observe the parallactic shifting of the same cloud-points, in the two illustrations, in a fixed direction. In each of the illustrations, two stars, α and β Aurigæ, appear. On account of the enormous distance, the lines of direction, in which one and the same star is seen simultaneously from different points of view, are parallel to one another. Hence the deviation of two corresponding cloud-points, in the illustrations, with regard to one and the same star, gives a measure for the parallax of those cloud-points, on the supposition that the focal distance of the photographic apparatus is known. The focal distance of the two sets of apparatus was precisely determined by the photographing of stars, and proved to be almost exactly 200 mm. In accordance with this the above-mentioned height of 81 kilometres was found.

The following peculiarities, which observation of luminous clouds has firmly established, are of great interest:—

(1) Luminous clouds had in general a very rapid movement from north-east to south-west. In some cases movements also took place in the opposite direction; but these were always much slower—and they were also much less frequent—than those first named.

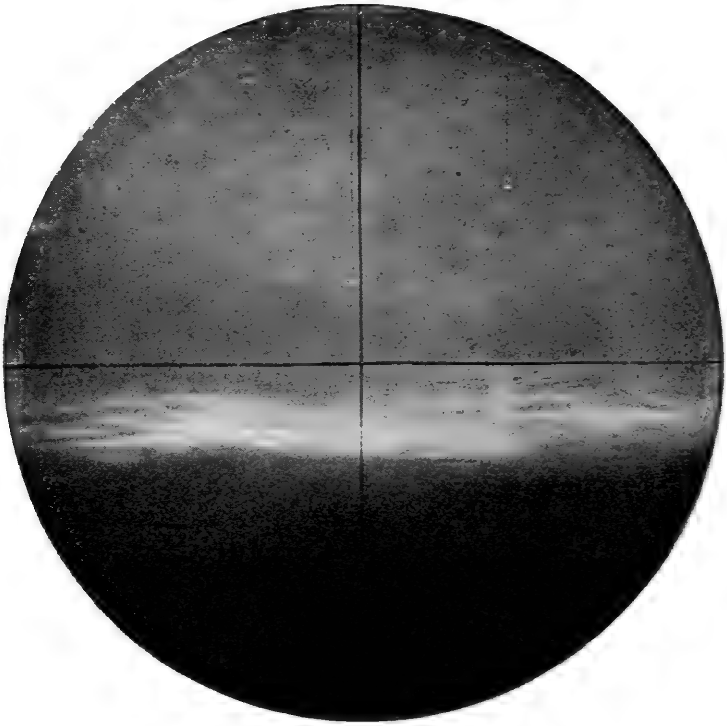

FIG. 2.

(2) Since their first appearance, luminous clouds have to a considerable extent waned. In the year 1890 they have displayed a beautiful brilliance during only about three nights; at other times the light was for the most part very feeble. Very probably we must connect with this decrease of light the fact that the apparent height at which the clouds have been seen, has been very much smaller in the last years than it was formerly.

(3) Luminous clouds present themselves generally much more brightly—therefore are more frequently visible—after than before midnight. While in the first years they appeared before midnight very frequently, they have done so in the last years very seldom. After midnight they still appear pretty often. Whether this distinction existed during the first years, was unfortunately not established, because the regular observations were then usually limited to the time before midnight.

O. JESSE.

NOTES.

THE anniversary meeting of the Royal Society will this year be held on Monday, December 1, St. Andrew's Day falling on a Sunday. The medals are to be given as follows:—The Copley Medal to Prof. Simon Newcomb, for his contributions to gravitational astronomy; the Rumford Medal to Prof. Heinrich Hertz, for his work in electro-magnetic radiation; a Royal Medal to Prof. David Ferrier, for his researches on the localization of cerebral functions; and a Royal Medal to Dr. John Hopkinson, for his researches in magnetism and electricity; the Davy Medal to Prof. Emil Fischer, for his discoveries in organic chemistry; and the first Darwin Medal to Mr. A. R. Wallace, for his independent origination of the theory of the origin of species by natural selection. The anniversary dinner will take place at the Hôtel Métropole.

LORD RAYLEIGH has been appointed an honorary member of the Bavarian Royal Academy of Science.

PROF. J. A. EWING, F.R.S., has been elected Professor of Mechanism and Applied Mathematics at Cambridge, in succession to Prof. Stuart.

MR. WILLIAM LEADBETTER CALDERWOOD, who was for several years naturalist to the Fishery Board for Scotland, has been appointed Director of the Laboratory for Marine Zoology at Plymouth.

SOME time ago the Phi Beta Kappa Society proposed that the four hundredth anniversary of the discovery of America should be signalized by a memorial history of American literature and science. Two prizes of 3000 dollars each were to be offered for the best general survey of American literature and science respectively; and, in addition to this, it was proposed that the preparation of an extensive and detailed account of scientific achievement should be prepared, the work for each department being entrusted to a specialist in that department. The New York *Nation*, which calls attention to the matter, speaks of this last undertaking as "the really serious task, and the only part of the scheme which possessed in a high degree the monumental character." We learn from the *Nation* that a committee having the project in charge is about to meet and confer upon the initiation of the work. The committee consists of the presidents of six of the most important American Universities, together with one or two other gentlemen of equal eminence.

IN the *Kew Bulletin* for November many interesting facts with regard to the cultivation of Liberian coffee are brought together. The same number contains an excellent account of the cola nut (*Cola acuminata*, R. Br.). In early times, cola nuts were supposed to be used merely as a means for rendering water sweet and palatable when drunk before or after meals. "But," says the *Bulletin*, "it was soon evident that they possessed other properties, and that they had been selected as if by intuition on account of the property which undoubtedly they did possess of supplying a necessary stimulus to those who have to endure an occasional or prolonged deficiency of animal food; for in West Africa, as in other parts of the tropics, the flesh of animals is often scarce and difficult to procure. The use of cola nuts to render water palatable may be compared to that of olives in European countries. The latter are well known to enhance the flavour of whatever is eaten after them. On the other hand, the power said to be possessed by cola nuts of staying the cravings of hunger, and of enabling those who eat them to endure prolonged labour without fatigue, is comparable to that ascribed to the leaves of the coca plant of Ecuador and Peru. In fact, cola nuts in Western Africa play the same part that *Erythroxylon Coca* does in South America."

ON Monday, the Master (Sir James Whitehead), the Wardens and Court of the Fruiterers' Company, and others, had an interview with the Lord Mayor at the Mansion House, to seek his aid in a project for the encouragement of the culture of British fruit. Sir James Whitehead, addressing the Lord Mayor, said that, having regard to the great success which had attended the recent exhibition of fruit at Guildhall, the Fruiterers' Company were now proposing to increase their operations in the same direction. Their idea was to have fruit shows in different parts of the country, similar to the annual shows of the Royal Agricultural Society of England, in co-operation with the local horticultural societies. During these shows there would be lectures on various subjects connected with the cultivation of fruit. It would be the aim of the Company to give the warmest encouragement to the various horticultural societies, and to stir up a spirit of emulation among the local and parochial organizations. The Company had arranged that the committee of experts who recently assisted them in connection with the Guildhall exhibition should meet once a month, and receive and answer questions on the subject of fruit culture. It was estimated that to carry out these objects a fund of about £20,000 would be necessary. It was believed that landed proprietors and the City Companies would be willing to aid this effort, and they might even obtain the assistance of a Government grant. What they asked the Lord Mayor to do was, first, to allow a great public meeting to be held at the Mansion House, and, secondly, to organize a Mansion House fund with the view of raising the necessary sum. The Lord Mayor cordially agreed to convene and preside over such a meeting as was suggested, but reserved his decision as to the raising of a Mansion House fund.

MR. SHIRLEY HIBBERD, the well-known horticulturist, died at his residence at Kew on Sunday. He was for many years editor of the *Gardener's Magazine*, and was the author of many works on horticulture. Mr. Hibberd was in his sixty-sixth year.

ON Saturday evening several shocks of earthquake were felt in the north-east of Scotland. The *Daily News* says that the first shock was experienced at 5.50 p.m. in Inverness, and that it lasted about 30 seconds. A good deal of damage was done to property by the falling of gables, chimneys, &c. The inhabitants were very much excited. Half an hour afterwards a second shock was experienced, but was not of so severe a character. About 6 o'clock a sharp shock of earthquake was felt at Forres. The disturbance was accompanied by a rumbling noise, with heaving and convulsion, which lasted from 15 to 20 seconds. It was felt over a radius of several miles. The *Times* says the earthquake was felt at Beauly, Inverness-shire, where many shops and houses were severely shaken, and furniture was thrown down. In Western Lovat a chimney-stack was knocked over. We learn from a correspondent at Nairn that "a slight vibration" was felt there and in the surrounding district "about 6 p.m."

AT the fourth annual general meeting of the Anthropological Society of Bombay, an address was delivered by the retiring President, Mr. Denzil Ibbetson. Speaking of the valuable contributions that might be made to anthropology by native inquirers, Mr. Ibbetson pointed out that sources of information are freely opened to them to which Englishmen can gain access only with difficulty. "It is through their agency alone," he said, "that we can hope to learn the rites and customs particular to women, rites and customs which I believe to possess a very special significance, as being in many cases handed down directly from the aboriginal women of the country, with whom the subsequent immigrants intermarried. And their facilities of communication with the masses are so infinitely greater than our own, that I look forward to the most valuable results so soon as we have a body of native gentlemen intelligently studying the anthropology of India. At present, in Upper India at any rate, a native who is sufficiently educated to understand the nature and object of our inquiries is too often hampered by his religious education, which causes him to describe the religion of the peasantry as it should be rather than as it is, and by his pride of caste, which prevents him from interesting himself in those whom he considers beneath his notice."

A PASSAGE in an appendix to Mr. Scott's last report on the administration of the Northern Shan States shows the extraordinary mixture of peoples and tongues in this region, and shows also what a task there is for the ethnologist of the future to unravel the tangled skein presented to him by the Shan State of Mainglin. The report says the population consists of Shans, Las, Was, Kachins, Shan-Taloks, Myen, and a tribe known as Mutso. The Las men dress like Shans, but their clothes are of black or dark-blue stuff. The women wear black coats and black *tameins*. The Was, both men and women, wear black coats and a striped black and white *lungi*. The Myen wear clothes like Shans, but black, and are said to shave the head, leaving only a pigtail like the Chinese. They are represented as speaking the same dialect as the Chinese Shans. The Mutso tribe is so called by the Shans from their being hunters. They, like the Las and Was, have a separate language, but in every tribe there are a good many men who understand Shan. The Myen tribe are said to be *nat*, or spirit, worshippers, but among the Las and Was there are a good many Buddhists.

IN the September number of the *Bulletin of the Italian Geographical Society*, Colonel C. Airaghi gives an account of an exploration in Dembelas, a region of the plateau of Northern Abyssinia, watered by the River Mareb. The memoir deals with the topography, geology, and natural history of the district, with the aid of diagrams. Considering the proximity to the equator, the climate is very mild, though the changes of temperature are often rapid. A general map, and the notes of his fellow-explorer, Captain St. Hidalgo, will appear in the next issue. The most important paper is Dr. Arthur Wolynski's on the population of the Caucasus. This is estimated at 6,171,400, of whom 1,217,400 are Mongols, mainly Tartars. Of the whites 1,854,000 belong to the native Caucasian races—these are classified carefully; 41,000 are Semites, mostly Jews; the remaining 3,059,000 are Aryans, almost all groups being represented. The Russians number nearly two millions, while Dr. Wolynski estimates the Armenians at 750,000, and the Persian group at 339,000.

THE Meteorological Sub-Committee of the Croydon Microscopical and Natural History Club is doing good work by collecting and publishing daily rainfall values at a number of stations in the counties of Kent and Surrey, together with brief general notes on the weather of each month. The Report for 1889 shows that the year began with a staff of thirty-eight observers, superintending forty-five stations.

IN the *Meteorologische Zeitschrift* for October, M. Nils Ekholm gives an account of a method on trial at the Meteorological Office of Stockholm, which seems likely to throw some light upon what has hitherto been a difficult matter to deal with, namely, the determination of the path taken by storms. He calculates, from the telegraphic weather reports, tables of the density of the atmosphere, and constructs from the data synoptic charts of this element, and finds that they give a better clue to the movements and origin of cyclones than the usual method of a comparison of the isobars and isotherms alone. He finds that storms move in the direction of the warmest and dampest air, parallel to the lines of equal density, leaving the rarer air to the right-hand. A few empirical rules are quoted from about a hundred cases which have been investigated.

MR. T. TUHLIN has recently published in the *Nova Acta* of the Royal Society of Sciences of Upsala, a paper on the nocturnal temperature of the air at different heights up to 24 feet, from hourly observations taken during the winters of 1887 and 1888, in the grounds of the Upsala Observatory. The observations were made mostly while snow lay upon the ground, both with thermometers with and without screens, and were intended to form a sequel to the series made by Mr. H. E. Hamberg during the summer season. The first part of the paper contains a *résumé* of the experiments made since 1778. The following are some of the chief results arrived at in the second part of the paper. The decrease of temperature by radiation from unprotected thermometers over snow remained almost constant at heights above half a metre. During clear nights the temperature increased with height, from two or three hours before sunset until two hours after sunrise, and the lower the temperature, the greater was the increase. During cloudy or foggy nights the temperatures at different heights were nearly equal; but if the clouds were high and thin, the increase of temperature with height was only slightly hindered. The surface of the snow was found to be colder than the surrounding air.

A CORRESPONDENT of *Die Natur* describes the following incident, which he himself observed. On the branch of a tree was a sparrow's nest, in which were some young sparrows, and not far off sat the mother. A male sparrow, coming along that way, was attracted by her, and began to make advances, which were steadily rejected. By and by he rested on a neighbouring branch, and the mother flew away in search of food for her young. No sooner had she departed than the disappointed suitor pounced down upon the nest, caught one of the young sparrows in his bill, went off with it a little way, and then dropped it, apparently rejoicing in its death.

PROF. F. W. PUTNAM lately brought under the notice of the Boston Society of Natural History some fresh evidence of the fact that man was in America contemporaneous with the mastodon and mammoth. This evidence is afforded by a rude figure unquestionably representing a mammoth, scratched on a portion of a Busycon shell found under peat in Clairmont County, Delaware. Around the shell were human bones, charcoal, bones of animals, and stone implements.

ALTHOUGH the adult crab-eater, cobia, ling, or coal-fish (*Elacate Canada*), as the species is variously designated, is well known, the young has escaped notice until recently. In August, 1887, Dr. T. H. Bean caught two specimens in Great Egg Harbour Bay, New Jersey; and these he has described in a Bulletin of the U.S. Fish Commission. Dr. A. K. Fisher, in some notes he has just contributed to the Proceedings of the U.S. National Museum, mentions that, in June 1876, he received a young fish of this species, measuring 95 mm. in length, from a fisherman who caught it in a minnow seine about a mile north of the village Sing Sing, New York, in the broad and shallow cove formed by the expansion of the Croton River as it enters the Hudson. Nothing could be learned of the habits of the young fish except that it was alone. This was true also of Dr. Bean's specimens; "so, presumably, the young must soon separate and lead a solitary life, as the adults are said to do." The subject is of some practical interest, because the crab-eater, in Dr. Fisher's opinion, is "entitled to prominence as a food-fish, not only on account of the delicate flavour of its flesh, but also for its suitable size."

Apropos of our notes on scientific guide-books for Switzerland, Messrs. Wesley and Son send us from their catalogue the titles of the following works:—"Tourist's Guide to the Flora of the Alps," by K. W. v. Dalla-Torre, translated by Bennett, 1886, 4*s*. 6*d*. "Tour of Mont Blanc and of Monte Rosa," by J. D. Forbes, 320 pp. text, with engravings and maps, Edinburgh, 1855, 6*s*. 6*d*. "Flore Analytique de la Suisse," by A. Gremli, Genève, 1885, 7*s*; also in English, 1889, 7*s*. 6*d*. "Flora der Schweiz," by J. Hegetschweiler, edited by Heer, with 8 plates, Zürich, 1840, 4*s*. "Sketches of Nature in the Alps," by F. v. Tschudi, 1856, 2*s*. 6*d*. (Contents: General Characteristics; Vegetable Life; Hunting of the Vulture, Chamois, Lynx, Fox, Wolf, Bear, Alpine Cattle, Glaciers, &c.). "The Tourist's Flora: a Descriptive Catalogue of the Flowering Plants and Ferns of the British Islands, France, Germany, Switzerland, Italy, and the Italian Islands," by J. Woods, with index, 586 pp. and plate, 1850, £2 15*s*.

A SECOND edition of Mr. Frederick E. Chapin's "Mountaineering in Colorado" (Sampson Low) has been published.

There are some most interesting illustrations in this book. With few exceptions, they have been made directly from negatives taken during the author's various expeditions. The reproductions are the work of the Boston Photogravure Company.

We have received from the publishers, Messrs. Macmillan and Co., a small book of "Illustrations and Diagrams" from the works of Dr. Geikie and others, that has been arranged by Mr. Cecil Carus-Wilson to illustrate, in the Oxford University Extension lectures, the geological courses delivered by him. In order to give elementary lectures on this subject to students, one must have a most liberal supply of diagrams, &c., and they must all be placed so that they may be conveniently seen. Again, when slides are used students have not time to copy them while on the screen, and in this way many important facts which could be remembered by the presence of a diagram are forgotten. By means of Mr. Carus-Wilson's hand-book these disadvantages will disappear, and the student will have good and trustworthy illustrations from which he will be able to draw more comprehensive and accurate conclusions than he could from his own rough sketches made at the time. The diagrams are printed on excellent paper, and at the foot of each is a short description, with the reference to the work from which it has been taken. The book is sold at cost price.

The Indian Press, Allahabad, has published a very good series of geographical text-books for Indian schools, by the late Prof. S. A. Hill, of Muir Central College, Allahabad. The series consists of three little volumes, the first two of which have reached a third edition. The third volume, which is new, treats chiefly of mathematical and physical geography.

The fifth edition of Prof. M. Foster's "Text-book of Physiology" (Macmillan) is being published. Part iii., which has just been issued, deals with the central nervous system. The work has been largely revised.

Messrs. Longmans and Co. are issuing the tenth edition of Quain's "Elements of Anatomy." The task of editing the work has been entrusted to Prof. E. A. Schäfer and Prof. G. D. Thane. We have received the first part of vol. i., and the first part of vol. ii. The former deals with embryology, and is edited by Prof. Schäfer; the latter with osteology, Prof. Thane being the editor.

The second edition of "The Fuel of the Sun," by W. Mattieu Williams, has been issued. As the work was originally published twenty years ago, the author contributes a preface to the new edition, giving "a brief outline summary of the bearings of the growth of knowledge upon the subjects of the several chapters."

Messrs. Baillière, Tindall, and Cox will publish in a few days an octavo volume (360 pages and 52 figures) entitled, "Researches on Micro-Organisms," by Dr. A. B. Griffiths. The work gives an account of recent researches in various branches of bacteriology.

The Naturalists' Publishing Company, Birmingham, have issued "The Naturalists' Annual and Directory for 1891," edited by the editor of the *Naturalists' Gazette*. It consists of a number of short scientific articles, by various writers, and a directory indicating "the Lepidoptera of the months."

The University College of Nottingham has published the Calendar for its tenth session. In a supplement the facts relating to the engineering department of the College are brought together.

Benzoyl fluoride, C_6H_5COF, has been prepared for the first time by M. Guenez in the laboratory of M. Moissan at the Parisian École de Pharmacie. It was obtained by the general reaction lately proposed by M. Moissan, heating silver fluoride with the corresponding chloride in a sealed tube. Equal molecular proportions of silver fluoride, AgF, and benzoyl chloride, C_6H_5COCl, were heated together for six hours in a sealed tube to a temperature of 190°. After allowing the tube and contents to cool, the drawn out sealed end was opened at the blow-pipe in order to permit of the escape of gaseous silicon tetrafluoride, which is formed in considerable quantity owing to the energetic action of benzoyl fluoride upon glass. The tube was then drawn out about the middle of its length, and bent over in a V shape; the benzoyl fluoride was thus readily distilled off from the residual silver chloride, the second limb of the V acting as a condensing tube. The product so obtained was found, as might be expected, to contain admixed benzoyl chloride. It was therefore reheated in a second sealed tube with a fresh quantity of fluoride of silver, and the product distilled in the same manner as before. The resulting benzoyl fluoride was found to be practically free from chloride. Benzoyl fluoride is a colourless liquid possessing an odour analogous to that of benzoyl chloride, but much more irritating, the least trace of its vapour producing a copious flow of tears. It boils at 145°, and readily ignites when heated in the air, burning with a flame bordered by a blue halo. It sinks in water, which liquid slowly decomposes it in the cold, with formation of hydrofluoric and benzoic acids—

$$C_6H_5COF + H_2O = C_6H_5COOH + HF.$$

In contact with solutions of caustic alkalies it is rapidly converted into fluoride and benzoate of the alkali, the reaction being almost instantaneous when the temperature is slightly raised. It attacks glass very vigorously, with liberation of gaseous silicon tetrafluoride; benzoic anhydride, containing a deposit of potassium fluoride, is found remaining in the corroded vessel.

$$6C_6H_5COF + K_2SiO_3 = SiF_4 + 2KF + 3(C_6H_5CO)_2O.$$

Benzoyl fluoride appears, therefore, to fulfil the expectations concerning it in resembling very closely its nearest analogue, benzoyl chloride, in properties, the differences being only those due to the more active nature of the halogen fluorine, and to the remarkable affinity of the latter element for silicon.

The additions to the Zoological Society's Gardens during the past week include an Indian Chevrotain (*Tragulus meminna* ♂) from India, presented by Mr. Greenberg; a Globose Curassow (*Crax globicera* ♂) from Mexico, presented by Mr. R. M. Pryor, F.Z.S.; two Long-eared Owls (*Asio otus*), British, presented by Mrs. Twickline; an Eyed Lizard (*Lacerta ocellata*, var.) from Southern Spain, presented by Mr. Francis Napier; a Black-headed Gull (*Larus ridibundus*), British, presented by Miss Lanze; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mr. C. J. Owen; a Cryptoprocta (*Cryptoprocta ferox*) from Madagascar, purchased; two Crested Porcupines (*Hystrix cristata*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Duplicity of α Lyræ.—At the meeting of the Royal Astronomical Society on November 14, Mr. A. Fowler exhibited some photographs of the spectrum of α Lyræ which indicate that it is a spectroscopic double of the β Aurigæ and ζ Ursæ Majoris type. The photographs were taken with the 10-inch refractor belonging to the Royal College of Science, with two prisms of $7\frac{1}{2}°$ each in front of the object-glass, and form part of a photographic study of stellar spectra recently commenced at Kensington by Prof. Lockyer with a special object. The evidence of duplicity of this kind of binary star depends upon the fact that when the two components are moving in opposite directions in the line of sight, the lines that are common in their spectra are displaced towards opposite ends of the spectrum, in accordance with Doppler's principle, and therefore appear double. When the motion is at right angles to the line of sight, there is, of course, no such displacement, and the lines therefore appear single. Hence, during a complete revolution the lines will twice reach a maximum separation and twice appear single. The principal lines in the spectrum of α Lyræ are due to hydrogen. These do not exhibit a duplication, because the separation is less than their thickness. A variation in their width, however, is very obvious. The K line of calcium is the next strongest, and is sufficiently fine and distinct to render the duplicity very apparent. Fourteen photographs of the spectrum have been taken from October 3 to November 4. The maximum separation of the K line was recorded on October 8 as 7·8 tenth-metres. On October 17, 28, and November 1, 8 p.m., the same line appeared single. At 8.30 p.m. and 10 p.m. on the last-named date, the separation was respectively 2·3 and 3·8 tenth-metres. A discussion of the data obtained from all the photographs shows that they are fairly satisfied by assuming a circular orbit, the plane of which passes through the sun, and the remarkably short period of revolution of about 24·68 hours. This period does not appear inconsistent with the relative orbital velocity of 370 miles per second indicated by the photograph taken on October 8, and is confirmed by the three photographs taken at short intervals on November 1. If 370 miles per second be taken as the maximum relative orbital velocity, the distance between the components is about 5,000,000 miles. The total mass will therefore be about 22·5 times that of the sun, and as there is no appreciable difference in the intensity of the K lines, the masses of the components are probably about equal. In the cases of β Aurigæ and ζ Ursæ Majoris, Prof. Pickering found, respectively, periods of 4 and 52 days, and maximum orbital velocities of about 150 and 100 miles per second.

Parallaxes of Nebulæ.—Prof. Holden proposes to determine the parallaxes of nebulæ by taking short exposure photographs of their nuclei, and measuring their positions relative to neighbouring stars, in a similar manner to the method adopted by Prof. Pritchard for the photographic determination of the parallaxes of stars. A short exposure photograph taken at Lick Observatory, of Σ 6 and the stars near it, indicates that the method is one from which good results may be obtained.

Catania Observatory.—Prof. Riccò has been appointed Director of the new Catania Observatory. The work of the Observatory will be principally connected with astronomical physics, celestial photography, meteorology, and seismology.

Washington Observations, Appendix II.—This consists of an account of the work done by Mr. Asaph Hall, on Saturn and its ring, extending over the years 1875–89. Besides giving details of every observation made by him, he sums up afterwards the results obtained, from which we gather the following information. From a series of observations of the white spot on the equator of the planet, he finds the time of rotation of Saturn to be 10h. 14m. 23·8s. ± 2·30s. mean time: this differs slightly from that obtained by Sir William Herschel, who gave 10h. 16m. 0·4s., and said that his result could not be in error by so much as two minutes. The ball of the planet during the fourteen years of observation has undergone very slight changes, with the exception of the white spot which broke out on December 7, 1876. Although a careful examination was made to find if a notch could be seen in the outline of the shadow of the ball on the ring, no such phenomenon was recorded. Of the principal rings, no division was recorded in the inner ring. The Cassini division gave the impression "of not being a complete separation, or that small particles of matter remain in this partly dark space." The Encke division of the outer ring, although specially looked for could not be definitely stated as a "real and permanent division," although a slight marking was seen at times.

In addition to numerous tables of measurements of the ball and of the various rings, the author adds three plates of the planet as it appeared under favourable conditions in the opposition of 1884.

BIOLOGICAL NOTES.

Rate of Growth in Corals.—But little is as yet known as to the rate of growth of corals under different conditions. In the third edition of Dana's "Coral and Coral Islands," a *résumé* will be found of all that is known about this subject up to 1890, but some very interesting details have been published by Alexander Agassiz in the August number of the *Bulletin of the Museum of Comparative Zoology at Harvard College*. A series of specimens are figured, which have been taken off the telegraph cable laid between Havana and Key West, in June 1888, from a portion that was repaired in the summer of 1881; so that the growths could not be more than about seven years. It is to be observed that this portion of the cable was laid at a depth of only from six to seven fathoms, and that the district in which it was laid was most favourably situated as regards food supply to the corals. Some of the specimens belong to species whose rates of growth have not yet been recorded; they are as follows:—*Orbicella annularis*, figured on plates 1 and 2. Verrill mentions that the thickness of this coral formed in sixty-four years was not more than about 8 inches; the specimens from the Havana cable grew to a thickness of 2½ inches in about seven years. *Manicina areolata*, Ehrenb., figured on plate 3, has grown to a thickness of 1 inch; while *Isophylla dipsacea*, Ag., figured on plate 4, shows a still more rapid growth, projecting 2½ inches above the cable. Of course it is quite possible that these corals are of less than seven years' growth, but it is not probable that more than a short time passed before some of the swarms of pelagic coral embryos which must have floated past the cable found a place of attachment thereon.

Tuomeya fluviatilis, Harvey.—Over three-and-thirty years ago the late Prof. W. H. Harvey bestowed this name on a rare and curious freshwater Alga sent to him from the United States by Prof. Tuomey, of Alabama. Harvey's description was published in the third part of his "Nereis Boreali Americana," but Harvey, as was his wont, sent a scrap of his plant to Kuetzing, who at once described and figured it as *Baileya america*. Prof. Farlow gives the priority to Harvey's name, and we believe he is right. The systematic position of this little Alga is a matter of some importance. Harvey says, "The plants referred to Batrachospermeæ naturally group themselves into two sub-orders, distinguished from each other by the habit of the frond, but closely related in structure and fructification, and these seem to me inseparably connected by the genus Tuomeya, which unites in itself the characters of the seemingly so dissimilar genera Batrachospermum and Lemanea;" but the specimens at his command were too imperfect to enable the complete structure to be made out, and until the other day no light was thrown upon the subject. In December 1888, Mr. Holden found it in some quantity in a brook near Bridgeport, Conn., and since then it has turned up in several distant localities in the United States. Mr. W. A. Setchell has lately published the results of a very detailed investigation of the structure and development of this form, as the result of work done in the Cryptogamic Laboratory of Harvard University. It grows on smooth rocks or stones, in brooks or small streams, preferring places where the current is accelerated; in a few rare cases it has occurred upon aquatic grasses; it seems to be easily cultivated, one batch of specimens, even under such treatment, producing the reproductive organs; the plant seldom exceeds 5 cm. in height, and is bushy and rigid, in this latter respect presenting a marked contrast to the larger species of Batrachospermum, which in size, colour, and manner of growth it much resembles, and with which it very frequently grows. When dried, it is non-adherent to paper, resembling in this some of the Lemanea. Each main filament is composed of a single row of cells placed end to end, the apical cell being in a state of active growth, here and there at intervals the older cells of the filament branch out into a di- or trichotomously branched ramellus, of which several may arise from the same node, and the branchlets from these, intertwining as they increase, form a dense mass of cells round the central filamentous axis, and finally make up a hollow cylindrical frond composed of two sets of cells, somewhat resembling the structure seen in some forms of Lemanea. Before, however, this hollow cylinder is fully formed, filaments are given off from the basal portions of the inner cells of the ramelli, which differ from the ramelli cells in being cylindrical and simple. These grow downwards, forming a dense cortical layer around the axis; some, however, grow obliquely outwards, even protruding themselves beyond the outer limits of the frond, and may possibly become detached, forming new plants. Both the antheridia and procarps are to be found on the same plant, but generally on separate portions of the frond; the antheridia in shape, colour, and character of contents exactly agree with those of Batrachospermum; they are borne at the tips of branches which arise from or near the nodes. These mostly pass out horizontally to the surface of the frond. The antheridial branches are at first unbranched; their ends just beneath the outer surface of the frond are two or three times branched in a corymbosely dichotomous fashion; the antheridia are apical, spheroidal; the antherozoids are solitary; for a short time after escape they are of an irregular shape, exhibit slight amœboid motion, but soon become globular and motionless. The female organs are borne upon especially modified procarpic branches; in the axil of one of the ramelli, arise one, sometimes more short branches strikingly different from any of the other outgrowths, made up of broad, stout cells. As these increase in length they generally become spirally twisted, and the cells on their convex sides develop short branches. The terminal cell of the branch produces the procarp, which in Tuomeya consists of a broadly ovoid trichophore, surmounted by a trichogyne several times longer than itself. After fertilization the trichophore begins to bud forth cells, which gradually become arranged in more or less concentric rows upon the surface of the trichophore; the further development was not seen, but it is surmised that strings of spores are then formed, as in Batrachospermum. Unfortunately the germination of the spores has not been witnessed, nor have very young plants yet been seen. Some further investigations as to the structure of cystocarps is also desirable, but we know that Mr. Setchell is continuing his researches, and we trust these will not end until the whole life-history of this very interesting fresh-water Alga is thoroughly understood. (Proceedings of the American Academy of Arts and Sciences, vol. xxv. p. 53, with a plate.)

Marine Algæ of Berwick-on-Tweed.—Mr. Edward A. L. Batters has recently published, from the Transactions of the Berwickshire Naturalists' Club for 1889, a most useful list of the marine Algæ of Berwick-on-Tweed. Many years have elapsed since the appearance of Dr. Johnston's list, and very numerous have been the alterations in nomenclature since those days. This new list is therefore all the more welcome, as it comes as a contribution towards a revision of the British Algæ, which the great advance in our knowledge that has been made since the publication of Harvey's splendid "Phycologia Brittanica" renders absolutely necessary. Mr. Batters's list contains 271 species. Comparing this with a few local lists conveniently at hand, we find in Le Joli's well-known "Cherbourg Algal Flora" 350 species; Debray, "Catalogue of the Algæ found at Dunkirk," gives 189 species; while Flahault's interesting account of his collecting for some six weeks at Croisic details 230 forms. Of those enumerated in the Berwick list no less than 78 species have been added to the British flora since the publication of Harvey's work. One minute form found presenting the appearance of tiny yellow-brown patches has been made by Reinke a new genus, Battersia; it belongs to the Sphacelariaceæ, and has doubtless been often overlooked. From a small encrusting thallus little patches of fruit bearing filaments arise. Several of the Algæ lately described by Bornet and Flahault as perforating species, chiefly in the substance of marine shells, such as *Gomontia polyrhiza* and *Mastigocoleus testarum*, are recorded. There is an index of genera and also figures of most of the new species.

DR. KOCH ON TUBERCULOSIS.

A SUPPLEMENT to the *British Medical Journal* contains "A Further Communication on a Remedy for Tuberculosis," translated from the original article published in the *Deutsche Medizinische Wochenschrift*, November 14, by Prof. Dr. Robert Koch, Berlin, as follows:—

Introduction.

In an address delivered before the International Medical Congress I mentioned a remedy which conferred on the animals experimented on an immunity against inoculation with the tubercle bacillus, and which arrests tuberculous disease. Investigations have now been carried out on human patients, and these form the subject of the following observations.

It was originally my intention to complete the research, and especially to gain sufficient experience regarding the application of the remedy in practice and its production on a large scale, before publishing anything on the subject. But, in spite of all precautions, too many accounts have reached the public, and that in an exaggerated and distorted form, so that it seems imperative, in order to prevent all false impressions, to give at once a review of the position of the subject at the present stage of the inquiry. It is true that this review can, under these circumstances, be only brief, and must leave open many important questions.

The investigations have been carried on under my direction by Dr. A. Libbertz and Stabsarzt Dr. E. Pfühl, and are still in progress. Patients were placed at my disposal by Prof. Brieger from his Poliklinik, Dr. W. Levy from his private surgical clinic, Geheimrath Dr. Fräntzel and Oberstabsarzt Kohler from the Charité Hospital, and Geheimrath v. Bergmann from the Surgical Clinic of the University.[1]

Nature and Physical Characters of the Remedy.

As regards the origin and the preparation of the remedy I am unable to make any statement, as my research is not yet concluded: I reserve this for a future communication.[2] The remedy is a brownish transparent liquid, which does not require special care to prevent decomposition. For use, this fluid must be more or less diluted, and the dilutions are liable to decomposition if prepared with distilled water; bacterial growths soon develop in them, they become turbid, and are then unfit for use. To prevent this the diluted liquid must be sterilized by heat and preserved under a cotton-wool stopper; or more conveniently prepared with a ½ per cent. solution of phenol.

Manner of using the Remedy.

It would seem, however, that the effect is weakened both by frequent heating and by mixture with phenol solution, and I have therefore always made use of freshly-prepared solutions. Introduced into the stomach, the remedy has no effect; in order to obtain a trustworthy effect, it must be injected subcutaneously. For this purpose we have used exclusively the small syringe suggested by me for bacteriological work; it is furnished with a small india-rubber ball, and has no piston. This syringe can easily be kept aseptic by absolute alcohol, and to this we attribute the fact that not a single abscess has been observed in the course of more than a thousand subcutaneous injections. The place chosen for the injection—after several trials of other places—was the skin of the back between the shoulder-blades and the lumbar region, because here the injection led to the least local reaction—generally none at all—and was almost painless.

Effect of Injections in Healthy Individuals.

As regards the effect of the remedy on the human patient, it was clear from the beginning of the research that in one very important point the human being reacts to the remedy differently from the animal generally used in experiments—the guinea-pig; a new proof for the experimenter of the all-important law that experiment on animals is not conclusive for the human being, for the human patient proved extraordinarily more sensitive than the guinea-pig as regards the effect of the remedy. A healthy guinea-pig will bear two cubic centimetres and even more of the liquid injected subcutaneously without being sensibly affected. But in the case of a full-grown healthy man 0·25 cubic centimetres suffice to produce an intense effect. Calculated by body weight, the 1500th part of the quantity, which has no appreciable effect on the guinea-pig, acts powerfully on the human being. The symptoms arising from an injection of 0·25 cubic centimetre I have observed after an injection made in my own upper arm. They were briefly as follows:—Three to four hours after the injection there came on pains in the limbs, fatigue, inclination to cough, difficulty in breathing, which speedily increased. In the fifth hour an unusually violent attack of ague followed, which lasted almost an hour. At the same time there was sickness, vomiting, and rise of body temperature up to 39°·6 C. After twelve hours all these symptoms abated. The temperature fell, until next day it was normal, and a feeling of fatigue and pain in the limbs continued for a few days, and for exactly the same period of time the site of injection remained slightly painful and red. The lowest limit of the effect of the remedy for a healthy human being is about 0·01 cubic centimetre (equal to 1 cubic centimetre of the hundredth solution), as has been proved by numerous experiments. When this dose was used, reaction in most people showed itself only by slight pains in the limbs and transient fatigue. A few showed a slight rise of temperature up to about 38° C. Although the dosage of the

[1] Dr. Koch here expressed his thanks to these gentlemen.

[2] Doctors wishing to make investigations with the remedy at present can obtain it from Dr. A. Libbertz, Lueneburger Strasse 28, Berlin, N.W., who has undertaken the preparation of the remedy, with my own and Dr. Pfühl's co-operation. But I must remark that the quantity prepared at present is but small, and that larger quantities will not be obtainable for some weeks.

remedy shows a great difference between animals and human beings—calculated by body weight—in some other qualities there is much similarity between them. The most important of these qualities is the specific action of the remedy on tuberculous processes of whatever kind.

The Specific Action on Tuberculous Processes.

I will not here describe this action as regards animals used for experiment, but I will at once turn to its extraordinary action on tuberculous human beings. The healthy human being reacts either not at all or scarcely at all—as we have seen when 0·01 cubic centimetre is used. The same holds good with regard to patients suffering from diseases other than tuberculosis, as repeated experiments have proved. But the case is very different when the disease is tuberculosis: the same dose of 0·01 cubic centimetre injected subcutaneously into the tuberculous patient caused a severe general reaction, as well as a local one. (I gave children, aged from 2 to 5 years, one-tenth of this dose—that is to say, 0·001 cubic centimetre; very delicate children, only 0·0005 cubic centimetre, and obtained a powerful but in no way dangerous reaction.) The general reaction consists in an attack of fever, which, generally beginning with rigors, raises the temperature above 39°, often up to 40°, and even 41° C.; this is accompanied by pain in the limbs, coughing, great fatigue, often sickness and vomiting. In several cases a slight icteric discolouration was observed, and occasionally an eruption like measles on the chest and neck. The attack usually begins four to five hours after the injection, and lasts from twelve to fifteen hours. Occasionally it begins later, and then runs its course with less intensity. The patients are very little affected by the attack, and as soon as it is over feel comparatively well, generally better than before it. The local reaction can be best observed in cases where the tuberculous affection is visible; for instance, in cases of lupus: here changes take place which show the specific anti-tuberculous action of the remedy to a most surprising degree. A few hours after an injection into the skin of the back—that is, in a spot far removed from the diseased spots on the face, &c.—the lupus spots begin to swell and to redden, and this they generally do before the initial rigor. During the fever, swelling and redness increase, and may finally reach a high degree, so that the lupus tissue becomes brownish and necrotic in places. Where the lupus was sharply defined we sometimes found a much swollen and brownish spot surrounded by a whitish edge almost a centimetre wide, which again was surrounded by a broad band of bright red.

After the subsidence of the fever the swelling of the lupus tissue decreases gradually, and disappears in about two or three days. The lupus spots themselves are then covered by a crust of serum, which filters outwards, and dries in the air; they change to crusts, which fall off after two or three weeks, and which, sometimes after one injection only, leave a clean red cicatrix behind. Generally, however, several injections are required for the complete removal of the lupus tissue. But of this more later on. I must mention, as a point of special importance, that the changes described are exactly confined to the parts of the skin affected with lupus. Even the smallest nodules, and those most deeply hidden in the lupus tissue, go through the process, and become visible in consequence of the swelling and change of colour, whilst the tissue itself, in which the lupus changes have entirely ceased, remains unchanged. The observation of a lupus case treated by the remedy is so instructive, and is necessarily so convincing, that those who wish to make a trial of the remedy should, if at all possible, begin with a case of lupus.

The Local and General Reaction to the Remedy.

The specific action of the remedy in these cases is less striking, but is perceptible to eye and touch, as are the local reactions in cases of tuberculosis of the glands, bones, joints, &c. In these cases swelling, increased sensibility, and redness of the superficial parts are observed. The reaction of the internal organs, especially of the lungs, is not at once apparent, unless the increased cough and expectoration of consumptive patients after the first injections be considered as pointing to a local reaction. In these cases the general reaction is dominant; nevertheless, we are justified in assuming that here, too, changes take place similar to those seen in lupus cases.

The Diagnostic Value of the Method.

The symptoms of reaction above described occurred without exception in all cases where a tuberculous process was present in the organism, after a dose of 0·01 cubic centimetre, and I think I am justified in saying that the remedy will therefore, in future, form an indispensable aid to diagnosis. By its aid we shall be able to diagnose doubtful cases of phthisis; for instance, cases in which it is impossible to obtain certainty as to the nature of the disease by the discovery of bacilli, or elastic fibres, in the sputum, or by physical examination. Affections of the glands, latent tuberculosis of bone, doubtful cases of tuberculosis of the skin, and such like cases, will be easily and with certainty recognized. In cases of tuberculosis of the lungs or joints which have become apparently cured we shall be able to make sure whether the disease has really finished its course, and whether there be not still some diseased spots from which it might again arise as a flame from a spark hidden by ashes.

The Curative Effect of the Remedy.

Of much greater importance, however, than its diagnostic use is the therapeutic effect of the remedy. In the description of the changes which a subcutaneous injection of the remedy produces in portions of skin changed by lupus I mentioned that after the subsidence of the swelling and decrease of redness the lupus tissue does not return to its original condition, but that it is destroyed to a greater or less extent, and disappears. Observation shows that in some parts this result is brought about by the diseased tissue becoming necrotic, even after one sufficient injection, and, at a later stage, it is thrown off as a dead mass. In other parts a disappearance, or, as it were, a melting of the tissues seems to occur, and in such case the injection must be repeated to complete the cure.

Its Action on Tuberculous Tissue.

In what way this process occurs cannot as yet be said with certainty, as the necessary histological investigations are not complete. But so much is certain, that there is no question of a destruction of the tubercle bacilli in the tissues, but only that the tissue enclosing the tubercle bacilli is affected by the remedy. Beyond this there is, as is shown by the visible swelling and redness, considerable disturbance of the circulation, and, evidently in connection therewith, deeply-seated changes in its nutrition, which cause the tissue to die off more or less quickly and deeply, according to the extent of the action of the remedy.

To recapitulate, the remedy does not kill the tubercle bacilli, but the tuberculous tissue; and this gives us clearly and definitely the limit that bounds the action of the remedy. It can only influence living tuberculous tissue; it has no effect on dead tissue, as, for instance, necrotic cheesy masses, necrotic bones, &c., nor has it any effect on tissue made necrotic by the remedy itself. In such masses of dead tissue living tubercle bacilli may possibly still be present, and are either thrown off with the necrosed tissue or may possibly enter the neighbouring still living tissue under certain circumstances. If the therapeutic activity of the remedy is to be rendered as fruitful as possible this peculiarity in its mode of action must be carefully observed. In the first instance, the living tuberculous tissue must be caused to undergo necrosis, and then everything must be done to remove the dead tissue as soon as possible, as, for instance, by surgical interference. Where this is not possible and the organism can only help itself in throwing off the tissue slowly, the endangered living tissue must be protected from fresh incursions of the parasites by continuous application of the remedy.

The Dose.

The fact that the remedy makes tuberculous tissue necrotic, and acts only on living tissue, helps to explain another peculiar characteristic thereof—namely, that it can be given in rapidly increasing doses. At first sight this phenomenon would seem to point to the establishment of tolerance, but since it is found that the dose can, in the course of about three weeks, be increased to 500 times the original amount, tolerance can no longer be accepted as an explanation, as we know of nothing analogous to such a rapid and complete adaptation to an extremely active remedy. The phenomenon must rather be explained in this way—that in the beginning of the treatment there is a good deal of tuberculous living tissue, and that consequently a small amount of the active principle suffices to cause a strong reaction; but by each injection a certain amount of the tissue capable of reaction disappears, and then comparatively larger doses are necessary to produce the same amount of reaction as before. Within certain limits a certain degree of habituation may be perceived.

As soon as the tuberculous patient has been treated with increasing doses for so long that the point is reached when his reaction is as feeble as that of a non-tuberculous patient, then it may be assumed that all tuberculous tissue is destroyed. And then the treatment will only have to be continued by slowly increasing doses and with interruptions, in order that the patient may be protected from fresh infection while bacilli are still present in the organism.

Whether this conception, and the inferences that follow from it, be correct, the future must show. They were conclusive as far as I am concerned in determining the mode of treatment by the remedy, which, in our investigations, took the following form.

The Treatment Applied to Lupus.

To begin with the simplest case, lupus; in nearly every one of these cases I injected the full dose of 0·01 cubic centimetre from the first. I then allowed the reaction to come to an end entirely, and then, after a week or two, again injected 0·01 cubic centimetre, continuing in the same way until the reaction became weaker and weaker, and then ceased. In two cases of facial lupus the lupus spots were thus brought to complete cicatrization by three or four injections; the other lupus cases improved in proportion to the duration of treatment. All these patients had been sufferers for many years, having been previously treated unsuccessfully by various therapeutic methods.

The Treatment Applied to Tuberculosis of the Bones and Joints.

Glandular, bone, and joint tuberculosis was similarly treated, large doses at long intervals being made use of; the result was the same as in the lupus cases—a speedy cure in recent and slight cases, slow improvement in severe cases.

The Treatment applied to Phthisis.

Circumstances were somewhat different in phthisical patients, who constituted the largest number of our patients. Patients with decided pulmonary tuberculosis are much more sensitive to the remedy than those with surgical tuberculous affections. We were obliged to lower the dose for the phthisical patients, and found that they almost all reacted strongly to 0·002 cubic centimetre, and even to 0·001 cubic centimetre. From this first small dose it became possible to rise more or less quickly to the same amount as is well borne by other patients.

Our course was generally as follows:—An injection of 0·001 cubic centimetre was first given to the phthisical patient; on this a rise of temperature followed, the same dose being repeated once a day, until no reaction could be observed. We then rose to 0·02 cubic centimetre, until this was borne without reaction; and so on, rising by 0·001, or at most 0·002, to 0·01 cubic centimetre and more. This mild course seemed to me imperative in cases where there was great debility. By this mode of treatment the patient can be brought to bear large doses of the remedy with scarcely a rise of temperature. The patients of greater strength were treated from the first, partly with larger doses, partly with rapidly repeated doses. Here it seemed that the beneficial results were more quickly obtained.

The action of the remedy in cases of phthisis generally showed itself as follows:—Cough and expectoration generally increased a little after the first injection, then grew less and less, and in the most favourable cases entirely disappeared; the expectoration also lost its purulent character, and became mucous.

As a rule the number of bacilli only decreased when the expectoration began to present a mucous appearance; they then from time to time disappeared entirely, but were again observed occasionally until expectoration ceased completely. Simultaneously the night sweats ceased, the patients' appearance improved, and they increased in weight. Within four to six weeks patients under treatment for the first stage of phthisis were all free from every symptom of disease, and might be pronounced cured. Patients with cavities, not yet too highly developed, improved considerably, and were almost cured; only in those whose lungs contained many large cavities could no improvement be proved objectively, though even in these cases the expectoration decreased, and the subjective condition improved. These experiences lead me to suppose that phthisis in the beginning can be cured with certainty by this remedy.[1]

[1] This sentence requires limitation in so far as at present no conclusive experiences can possibly be brought forward to prove whether the cure is lasting. Relapses naturally may occur; but it can be assumed that they may be cured as easily and quickly as the first attack. On the other hand, it seems possible that, as in other infectious diseases, patients once cured may retain their immunity. This, too, must, for the present, remain an open question.

Effect in Advanced Cases of Phthisis.

In part this may be assumed for other cases when not too far advanced; but patients with large cavities, who almost all suffer from complications caused, for instance, by the incursion of other pus-forming micro-organisms into the cavities, or by incurable pathological changes in other organs, will probably only obtain lasting benefit from the remedy in exceptional cases. Even such patients, however, were benefited for a time. This seems to prove that, in their cases, too, the original tuberculous disease is influenced by the remedy in the same manner as in the other cases, but that we are unable to remove the necrotic masses of tissue with the secondary suppuration processes.

The thought suggests itself involuntarily that relief might possibly be brought to many of these severely afflicted patients by a combination of this new therapeutic method with surgical operations (such as the operation for empyema), or with other curative methods. And here I would earnestly warn people against a conventional and indiscriminate application of the remedy in all cases of tuberculosis. The treatment will probably be quite simple in cases where the beginning of phthisis and simple surgical cases are concerned; but in all other forms of tuberculosis medical art must have full sway by careful individualization, and making use of all other auxiliary methods to assist the action of the remedy. In many cases I had the decided impression that the careful nursing bestowed on the patient had a considerable influence on the result of the treatment, and I am in favour of applying the remedy in proper sanatoria as opposed to treatment at home and in the out-patient room. How far the methods of treatment already recognized as curative—such as mountain climate, fresh-air treatment, special diet, &c.—may be profitably combined with the new treatment cannot yet be definitely stated, but I believe that these therapeutic methods will also be highly advantageous when combined with the new treatment in many cases, especially in the convalescent stage.[1] The most important point to be observed in the new treatment is its early application. The proper subjects for treatment are patients in the initial stage of phthisis, for in them the curative action can be most fully shown, and for this reason, too, it cannot be too seriously pointed out that practitioners must in future be more than ever alive to the importance of diagnosing phthisis in as early a stage as possible. Up to the present the proof of tubercle bacilli in the sputum was considered more as an interesting point of secondary importance, which, though it may render diagnosis more certain, could not help the patient in any way, and which, in consequence, was often neglected. This I have lately repeatedly had occasion to observe in numerous cases of phthisis which had generally gone through the hands of several doctors without any examination of the sputum having been made. In future this must be changed. A doctor who shall neglect to diagnose phthisis in its earlier stage by all methods at his command, especially by examining the sputum, will be guilty of the most serious neglect of his patient, whose life may depend on this diagnosis, and the specific treatment at once applied in consequence thereof. In doubtful cases medical practitioners must make sure of the presence or absence of tuberculosis, and then only the new therapeutic method will become a blessing to suffering humanity, when all cases of tuberculosis are treated in their earliest stage, and we no longer meet with neglected serious cases forming an inextinguishable source of fresh infections. Finally, I would remark, that I have purposely omitted statistical accounts and descriptions of individual cases, because the medical men who furnished us with patients for our investigations have themselves decided to publish the description of their cases, and I wish my account to be as objective as possible, leaving to them all that is purely personal.

ON THE INCUBATION OF SNAKES' EGGS.[2]

Most Reptilia are oviparous, but certain of the Lacertilians, and many Ophidians, especially vipers and sea-snakes, are ovo-viviparous—that is to say, the eggs are hatched within the mother, or, as sometimes occurs, during the process of parturition. This is the case with the English viper.

[1] As regards tuberculosis of brain, larynx, and miliary tuberculosis, we had too little material at our disposal to gain proper experience.

[2] By Walter K. Sibley, M.B., B.C., B.A. Camb., Assistant Physician to the North-West London Hospital. (Substance of a paper read before the Biological Section of the British Association at Leeds, September 1890.)

There has not been much written on the hatching of snakes' eggs. Almost the first literature of the subject appears to be some observations of M. Valenciennes made in 1841, at the Jardin des Plantes in Paris, and published in the *Comptes rendus*, on a Python (*Python bivittatus*) which was about 10 feet long. This reptile, in the beginning of May, deposited fifteen eggs: it coiled itself up over them for fifty-six days, after which period eight of the eggs hatched, and the young snakes came out, each measuring about half a metre in length. With regard to the temperature of the mother, he says, there was a marked increase of temperature during the whole period of incubation, which was highest at the commencement, and gradually diminished till the close.

In 1862, Sclater, in the Proceedings of the Zoological Society, described a Python (*Python sebæ*) which incubated her eggs, one hundred in number, for eighty-two days, at which period they were removed, none having hatched, and on examination it was found that five or six contained embryos. With regard to the temperature, he states that, in every observation, the female was several degrees warmer than the male; both being kept under similar conditions. Double observations were always made, one with the thermometer placed on the surface of the body, and the other by placing it between the folds. The differences in the temperature of the snake's body and of the surrounding air was higher by from 2°·8 to 12°·4 F., taken on the surface of the animal, and from 6°·8 to 20°·0 F., taken between the folds of the skin.

In the same year Colonel Abbott recorded that he had in his possession in India a female boa, which incubated her eggs, forty-eight in number, for three months, at the end of which period, on opening one of the shells, a live fully-formed young one was found.

In 1880, Forbes carried on some investigations with the eggs of *Python molurus* in the Zoological Society's Gardens. The snake was some 12 feet long, and on the night of June 5-6, deposited about twenty eggs, and then coiled herself around them, almost completely concealing them from view. She continued to cover the eggs for a period of six weeks, never eating during the whole time, and apparently only once leaving the eggs for a few hours one morning early in July.

On July 18—that is, forty-three days after—the eggs revealing evidences of decomposition they were removed, and one or two were found to contain embryos.

From June 14—that is, nine days after the eggs were laid—till they were removed on July 18, careful temperatures were taken every two or three days between the hours of 12 and 2 p.m. The temperature was taken both of the incubating female and also of the male, which was kept under similar circumstances in the next cage, the same methods being employed as in Sclater's experiments just described. The temperature was always found to be highest when that of the air in the cages was also highest. The temperature of the female was higher and more constant than that of the male. The greatest difference between that of the snake and that of the air was 8°·3 F. for the male, and 9°·6 F. for the female, taken on the surface; and 11°·6 F. for the male, and 16°·7 F. for the female, taken between the coils of the skin. It will be noticed that Valenciennes, who kept his snakes much colder,[1] records a difference of as much as 38°·7 F. (21°·5 C.), and some of his eggs hatched, which was not the case with Forbes's; also the later observer does not record a steady fall of the temperature throughout the incubation as did the former.

The common English snake (*Natrix torquata*) lays its eggs, varying in number from about fifteen to thirty, principally in manure-heaps, but also in holes and crevices between or under stones. It is usually stated they are laid in the autumn, but I have frequently found them towards the end of July, and one snake I had in confinement laid them as early as the 11th of that month. The shells being very thin and soft they require very delicate handling, the eggs being readily injured.

When laid under stones or in crevices, they are protected from the immediate pressure of the earth, and when deposited in manure which is much bound together by leaves and straw, &c., they are not individually subjected to much pressure. It must also be noticed that the eggs are usually found very close to the surface, and if laid deep in the manure heap, they, as a rule, do not hatch, although if examined late in the season the young snakes are found in them often completely formed, but dead. When first laid, the eggs are swollen out and full, and many or all the eggs are firmly bound together by adhesive medium. The egg-shell, if examined with the microscope, is found to consist of peculiar glistening fibres arranged in many separate layers. Between the outer layers only a small quantity of calcareous matter is present, and these fibres appear to be closely fitted together. There are seen in fresh, or better in specimens hardened in chromic acid, ten or more layers laid very closely one upon the other. The outer layers differ from the others in that they contain many rather club-shaped bodies of very different thicknesses and appearances placed between the other fibres.

The eggs are at first of a whitish straw colour. As time goes on, they become somewhat darker and then of a brown colour, and finally very dark; but these colour changes do not occur evenly over the whole shell, but in patches, and to a very varying extent. At the same time the regular outline is gradually lost, the shell shrivels, loses its original elasticity, and so at this stage impressions made upon the surface remain permanent. The diminution in actual bulk of the egg is probably due to evaporation of water from its substance. It is chiefly the extreme delicacy of the eggs, also the difficulty of keeping them in the requisite amount of moisture, that makes them so very hard to hatch artificially. But all these difficulties may with care be overcome, as I will proceed to describe.

On July 22, 1889, I found, in the manure of a cucumber-frame in Surrey, some seventy snakes' eggs in two masses, close together, and probably deposited by at least two snakes. The eggs were apparently of recent date, but showed great differences in the stage of their development—even those which were clearly laid by the same female. After removing some eggs for immediate examination, the rest were covered up again by the manure and left.

On September 8 they were again uncovered, and some were removed and taken to London. One of the eggs being opened at this period, the embryo snake was fairly well formed, and movements were visible but feeble. The eggs were brought to London on September 8, and on the 9th some were placed in an ordinary bacteriological incubator regulated for a temperature of 32° C. (89°·6 F.). The eggs were placed in open glass dishes with a small quantity of dung laid both at the bottom of the dish and also partially covering the eggs. Some of the dishes were left open, and others were protected by a piece of glass loosely laid over, but allowing the air to freely circulate, and were kept perpetually moist by cotton wool soaked in water. At the same time some eggs were placed under similar conditions in the atmosphere of the room, the temperature of which was maintained at about 17° C. (62°·6 F.). On September 17, the incubator leaked and had to be repaired, and during this period the eggs from it were left in the room temperature—namely, about 17° C.; the eggs being replaced in the incubator again on September 25.

On September 27, two of the eggs which had been kept all the time in the room temperature, showed signs of hatching—that is, the heads of the young snakes had broken through the shells, temperature 19° C. (66°·2 F.). These were noticed at 10 p.m. The next morning at 10 a.m., the hatching eggs presented the same appearances—that is, the heads only were out of the shells. The dish with these eggs was then placed on the top of the incubator at about a temperature of 24° C. (75° F.). At 1 p.m. the condition was unchanged, and at 10 p.m. both snakes were quite out of their shells.

On the same day, that is, the 28th, at 10 p.m., the head of one of the snakes inside the incubator was seen; at 10 the next morning this snake was quite free from its shell.

During the next few days several more eggs hatched, both those inside and those outside the incubator.

Some eggs, which were kept in a tin of manure in the room atmosphere of about 18° (64°·4 F.) since September 8, were on the 25th placed outside the window. During the night the temperature registered a minimum of 1°·5 C. (35° F.). On the 26th, they were brought inside again, and on the 27th they were placed in a temperature of 26° C. (78°·8 F.). In the course of time some of these eggs hatched with the others. The eggs in the incubator were placed at first on their sides, but on the 28th some were placed on their ends, and in both positions they appeared to hatch equally well.

The period of incubation of the eggs was thus about seventy-five to ninety days; the python, as described by Valenciennes,

[1] The extreme temperatures of the air recorded by Valenciennes, who took his observations when the cages were coldest, *i.e.* before the fresh hot water was put in, were 17°, and 23° C. (62°·6 and 73°·4 F.) respectively. The temperature of the two cages in which the animals were kept was only on three occasions less than the highest in Valenciennes' series.

being fifty-six days. It was noticed that many days often elapsed between the hatching of the eggs of the same lot—even those kept under similar circumstances. The differences in the actual stage of development of the eggs when first laid may possibly explain the apparent differences in the dates of hatching.

On July 11, 1890, a snake I had in confinement laid eighteen eggs. Some of these were placed at a temperature of 16°-20° C. (61°-68° F.): at the end of October, not being hatched, they were opened, and found to contain fully-formed young ones, but these were all dead. Other eggs from the same lot, which was laid on July 11, were sent into the country and placed in a manure-heap; on September 9, an egg being opened, the embryo snake was nearly formed, but there were no movements visible; on September 24 these eggs began to hatch—that is, after an incubation of seventy-five days.

From the first set of experiments it did not appear that the actual temperature influences to any great degree the period of incubation, or at least not after the first few weeks. (In the cases described it would appear that the eggs had been deposited some seven weeks before they were removed, and then kept artificially from three weeks to a month before they hatched.) Also, that exposure to the atmosphere does not destroy their vitality, provided they are kept fairly moist, some having hatched after several days' full exposure to the air of the room; and that they may be exposed to rather low temperatures, at least for a few hours, and yet finally hatch. As might be expected, some eggs which were placed in small glass pots and hermetically sealed did not hatch.

The process of hatching was very interesting to watch. At first a slit appeared in the uppermost part of the egg, whether the egg was placed on the side or on one end; most usually the slit rapidly became a **V**-shaped one, which in shape and position corresponded to the snout of the young reptile—that is to say, the apex of the **V** corresponding to the tip of the lower jaw. The snakes would often remain for some hours in this position, with just their snouts out, and, when disturbed, would withdraw these into the shells again. In a state of nature I have seen them when completely out of the shell, retreat into it again when disturbed. When first out of the shell, the young snakes were very smooth and velvety to the touch; there was usually some opacity about the cornea, which disappeared after a few hours; the yellow ring on the neck was well marked from the very first. They were about 15 cm. (6 inches) in length, and weighed about 3 grammes (45 grains); the eggs themselves weighed about 6 grammes (80 to 90 grains). One cast its skin within a few days after birth, and died. Occasionally they were hatched with the yolk-sac adherent, and in these instances always died. From the first the snakes were very lively, and within a very few days produced the characteristic hissing noise when provoked.

Many problems in connection with the subject of the incubation of eggs might be mentioned. It would be interesting to ascertain definitely what are the maximum and minimum temperatures at which the vital processes can take place in an incubating egg. There is probably an optimal temperature, or one at which the process proceeds most rapidly or most favourably. So also it might be asked, Is the optimal temperature the same for all kinds of eggs—those, for instance, of various forms of birds and those of snakes and lizards? Is the increase of temperature, both of the incubating bird and of the incubating python, essential to the hatching of the eggs? What is the reason of the differences in the incubation periods between different birds? Why, for instance, do pigeons' eggs hatch in fourteen days, hens' three weeks, turkeys' a month, and swans' six weeks?

We know that if a hen's egg be maintained for some twenty-one days at a temperature of about 40° C. it will hatch; but I am not aware of any experiments to ascertain if they will hatch at a temperature considerably under or much over this, and what is the minimum temperature at which they will hatch at all? In the case of many of the micro-organisms, bacteriologists have found the actual limits of temperature within which the various species grow, and also that most of them have an optimal temperature—that is, one at which these lowest forms of vegetable life grow most luxuriantly.

Literature.—Valenciennes, *Comptes rendus de l'Académie des Sciences*, 1841; Sclater, Proceedings of the Zoological Society, London, 1862; Abbott, Proceedings of the Zoological Society, London, 1862; Lataste Fernand, Paris, 1877; Forbes, Proceedings of the Zoological Society, London, 1880; Fisher, *Der Zoolog. Garten*, Bd. 26, 1886.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Among the lectures which are being delivered this term, we notice the following:—Electricity, Prof. Clifton; Physical Optics, Mr. Walker; Ureas and Uric Acid, Prof. Odling; Surfaces of the Second Order, Prof. Sylvester; Disturbed Elliptic Motion, Prof. Pritchard.

In the Morphological Department Prof. Ray Lankester is giving a general course on Animal Morphology, and Mr. Minchin, who has been appointed Junior Demonstrator, is lecturing on the Porifera.

The arrangements for the instruction of medical students in physiology have been considerably improved.

The Burdett-Coutts Geological Scholarship has been awarded to Mr. F. W. Howard, of Balliol.

In the Report of the Visitors of the University Observatory it is stated that Prof. Pritchard will shortly publish an enlargement of his lectures on Disturbed Elliptic Motion.

The following examiners have been appointed for next year:—Physics, Mr. Baynes and Mr. H. G. Madan; Chemistry, Prof. Tilden; Animal Morphology, Mr. Poulton and Mr. Bourne; Physiology, Mr. F. Gotch.

The statute respecting the admission of women to examinations in medicine, which has formed the subject of a good deal of controversy, has been rejected in Congregation by 79 votes to 75.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for August contains:—On the origin of vertebrates from Arachnids, by W. Patten (plates xxiii. and xxiv.). As a full description of the author's observations could not be published without considerable delay in this article of sixty pages, he gives a short account of the facts bearing directly on the subject, and at the same time presents his theoretical conclusions. Recognizing the "Annelid theory" as sterile, the author thinks that since vertebrate morphology reflects, as an ancestral image only, the dim outlines of a segmented animal, but still not less a vertebrate than any now living, it is clear that the problem must be solved, if at all, by the discovery of some form in which the specialization of the vertebrate *head* is already foreshadowed. While, since of all invertebrates, concentration and specialization of head segments is greatest in the Arachnids, it is in these, on *a priori* grounds, that we should expect to find traces of the characteristic features of the vertebrate head. Finding, from time to time, confirmation of this preconceived idea, as the unexpected complexity of the Arachnid cephalothorax revealed itself, he feels justified in formulating a theory that *Vertebrates are derived from the Arachnids*.—On the origin of vertebrates from a Crustacean-like ancestor, by W. H. Gaskell, F.R.S. (plates xxv. to xxviii.). This paper is but chapter one of a very important memoir, which approaches the subject of the ancestry of the vertebrates from a different standpoint from that of Dr. Patten. In previous papers the author had pointed out that the vertebrate nervous system is composed of nervous material grouped around a central tube which was originally the alimentary canal of the invertebrate from which the vertebrate arose, and that the physiology and anatomy of this system both best fit in with the assumption that the invertebrate ancestor was of the Crustacean, or at least of a proto-Crustacean type. In both these papers the author promised to point out the confirmation of this theory, which is afforded by the study of the lowest vertebrate nervous system, viz. that of the Ammocœtes form of Petromyzon. This promise he redeems in this paper, in which, to bring out as prominently as possible the theory, he discusses the nervous system of the Ammocœtes in terms of the Crustacean. Taking separately the prominent features of the alimentary canal and central nervous system of a Crustacean-like animal, he indicates how each one exists in the nervous system of the Ammocœtes. In a second chapter it will be pointed out how the present alimentary canal arose by the prolongation of a respiratory chamber.—On the development of the atrial chamber of Amphioxus, by E. Ray Lankester, F.R.S., and Arthur Willey (plates xxix. to xxxii.). The period of development was that before Hatschek's well-known work stops short. Series of sections were prepared in order to ascertain the mode in which the atrial chamber takes its origin, and the subsequent history of the gill-slits, viz. as to how the slits on the left side of the pharynx originate. The relation of the larval to the adult mouth, and the details of the curious process of the movement of the mouth from a unilateral to a median position, were also included in the scope of the author's inquiries.

American Journal of Science, November 1890.—Further study of the solar corona, by Frank H. Bigelow. The author has made a series of measures upon photographs of coronal streamers taken in 1878, July 29, by Prof. Asaph Hall. This has been done with a view of testing the validity of the equation that he has assigned to the coronal curves in a discussion of them by spherical harmonics.—Superimposition of the drainage in Central Texas, by Ralph S. Tarr.—A description of the "Bernardston Series" of metamorphic Upper Devonian rocks (continued from October), by Prof. B. K. Emerson.—Analysis of rhodochrosite from Franklin Furnace, New Jersey, by P. E. Browning.—A re-determination of the atomic weight of cadmium, by Edw. A. Partridge.—On the occurrence of nitrogen in uraninite, and on the composition of uraninite in general; condensed from a forthcoming Bulletin of the U.S. Geological Survey, by W. F. Hillebrand. It is found that nitrogen exists in uraninite in quantities up to over 2·5 per cent., and seems generally to bear a relation to the amount of UO_2 present. This is the first discovery of nitrogen in the primitive crust of the earth.—Anthophyllite from Franklin, Macon County, North Carolina, by S. L. Penfield.—Pre-glacial drainage and recent geological history of Western Pennsylvania, by P. Max Foshay.—On the so-called perofskite from Magnet Cove, Arkansas, by F. W. Mar.—Experiments upon the constitution of the natural silicates (continued from October), by F. W. Clarke and E. A. Schneider.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, November 4.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, September, and October, 1890, and called special attention to several of them. Among these were a young male example of the Wild Cattle of Chartley Park, Staffordshire, presented by Earl Ferrers; a Water-Buck Antelope (*Cobus ellipsiprymnus*) from the Somali Coast, presented by Mr. George S. Mackenzie; an example of the Horned Screamer (*Palamedea cornuta*), obtained by purchase; and a young female of Speke's Antelope (*Tragelaphus spekii*), presented by Mr. James A. Nicolls.—The Secretary exhibited, on behalf of Dr. A. B. Meyer, a coloured photograph of a singular variety of the Rose-coloured Pastor (*Pastor roseus*), with a red head, obtained near Sophia; and read a note from Dr. Meyer on this subject.—Mr. G. A. Boulenger made some remarks on an early reference to the Syrian Newt (*Molge vittata*) in Shaw's "Travels," published in 1738.—Mr. J. J. Lister gave an account of his recent visit to the Phœnix Islands, Central Pacific, and exhibited specimens of the birds and eggs obtained there.—Mr. Smith Woodward exhibited and made remarks upon the calvarium of an adult male *Saiga tatarica* from the Pleistocene deposits of the Thames Valley. The specimen had been obtained by Dr. J. R. Leeson from recent excavations in Orleans Road, Twickenham, and was the first trace of this Antelope discovered in Britain.—Mr. W. T. Blanford read a paper on the Gaur (*Bos gaurus*) and its allies, with especial reference to the exhibition of the first living Gaur ever brought to Europe in the Society's Gardens. He described the characters and geographical range of the three allied species of flat-horned taurine Bovines—the Gaur or Sladang (Bison of Indian sportsmen), the Gayal or Mithan (*Bos frontalis*), and the Banteng (*Bos sondaicus*); and he discussed the question whether *B. frontalis* is ever found in the wild state.—A communication was read from Dr. A. B. Meyer, containing the description of a new species of Squirrel from the Philippine Islands, which he proposed to call *Sciurus cagsi*.—Mr. R. Lydekker read a paper on a Cervine jaw from Pleistocene deposits in Algeria, which appeared to indicate the former existence in that country of a large Deer allied to *Cervus cashmirianus*. For this form Mr. Lydekker proposed the name *Cervus algericus*.—A communication was read from Dr. A. Günther, F.R.S., on the skull of the East African Reed-Buck. In this paper Dr. Günther described the skull of an Antelope obtained by Mr. H. C. V. Hunter in Masai Land, which he identified with *Cervicapra bohor* (Rüppell) from Abyssinia. He pointed out the differences from the skull of the South African species, for which the name *Cervicapra redunca* (Pallas) is generally employed.—Mr. P. Chalmers Mitchell described a graphic formula, designed for the purpose of representing geographical distribution. The regions were indicated by lines, the sub-regions by symmetrically placed numbers. This formula could be drawn rapidly, and printed without engraving.—Mr. W. L. Sclater read the description of a Jerboa from Central Asia, which he proposed to refer to a new genus and species of Dipodinæ under the name *Eucoreutes naso*.

Entomological Society, November 5.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Lord Walsingham announced the death of Mr. Atkinson, of the Indian Museum, Calcutta.—Mr. A. H. Jones exhibited a number of Lepidoptera collected in June last near Digne, Basses Alpes, including *Papilio Alexanor; Parnassius Apollo*, larger and paler than the Swiss form; *Anthocharis tagis*, var. *Bellezina; Leucophasia Duponcheli; Thecla spini; Thecla ilicis*, var. *cerri; Lycæna argiades*, var. *corretas; Melitæa deione*; and *Argynnis Euphrosyne*.—Mr. W. E. Nicholson also exhibited a collection of Lepidoptera, formed near Digne last June, which included very large specimens of *Papilio Machaon; P. Podalirius; Thais rumina*, var. *medesicaste*, larger and redder than the Mediterranean specimens; *Apatura ilia*, var. *clytie; Argynnis adippe*, var. *cleodoxa; A. Daphne; Melanargia galatea*, var. *leucomelas*; and many others.—Mr. C. O. Waterhouse exhibited the wings of a large species of *Attacus*, split in halves longitudinally so as to show the upper and lower membranes.—Dr. D. Sharp, F.R.S., exhibited a photograph he had received from Prof. Exner, of Vienna, showing the picture obtained at the back of the eye of *Lampyris splendidula*. He stated that this picture is continuous and not reversed, and shows the outlines of lights and shades of objects at a distance as well as of those closer to the eye.—Mr. H. Goss exhibited a specimen of *Zygæna filipendulæ*, var. *chrysanthemi*, which he had taken at Rhinefield, in the New Forest, on July 15 last. Dr. P. B. Mason said this variety was known on the continent of Europe, and was figured by Hübner in his "Sammlung," a copy of which work he exhibited. He added that he possessed a similar specimen of this variety taken in Wyre Forest, Worcestershire. Colonel Swinhoe stated that he possessed a similar variety of a species of *Syntomis*.—The Rev. Dr. Walker exhibited seven varieties of *Melanippe thuleana*, nine of *Coremia munitata*, and a few of *Noctua conflua*, illustrating the varied forms of these species occurring in Iceland. Dr. Mason said that the only British specimens of *N. conflua* which he had seen resembling the Iceland form of the species were taken at Wolsingham, Durham.—Mons. A. Wailly exhibited and remarked on a number of Lepidoptera from Japan. The collection comprised about thirty species, eleven of which, it was stated, were not represented in the British Museum collections.—Mr. A. C. Horner exhibited a number of rare species of Coleoptera, including *Homalota crassicornis*, Gyll., *H. humeralis*, Kr., and *Euryporus picipes*, Pk., collected at Church Stretton, Shropshire; and also *Amara nitida*, Sturm., *Oxypoda amæna*, Fair., *Homalota testaceipes*, Heer, and *Lithocharis apicalis*, Kr., from the neighbourhood of Tonbridge.—Herr Meyer-Darcis exhibited a specimen of *Termitobia physogastra*, Gangelb., a new genus and species of *Brachelytra* obtained in a white ants' nest from the Congo. Dr. Sharp commented on the interesting nature of the exhibition.—Colonel Swinhoe exhibited a collection of moths from Southern India, which comprised about forty species. He also read a paper, describing these species, entitled "New Species of Moths from Southern India."—The Rev. T. A. Marshall communicated a paper entitled "A Monograph of British Braconidæ, Part IV."—Lord Walsingham read a paper entitled "African Micro-Lepidoptera," containing descriptions of seventy-one new species, and of the following nine new genera, viz. *Autochthonus* (type *A. chalybiellus*, Wlsm.), *Scalidoma* (type *Tinea horridella*, Wkr.), *Barbaroscardia* (type *B. fasciata*, Wlsm.), *Odites* (type *O. natalensis*, Wlsm.), *Idiopteryx* (type *Cryptolechia obliquella*, Wlsm.), *Microthauma* (type *M. metallifera*, Wlsm.), *Licmocera* (type *L. lyonetiella*, Wlsm.), *Oxymacharis* (type *O. niveocervina*, Wlsm.), and *Micropostega* (type *M. æneofasciata*, Wlsm.). Several European and American genera were recorded as new to the African fauna; and the occurrence of one Australian and two Indian genera was also noted.

Linnean Society, November 6.—Prof. Stewart, President, in the chair.—Mr. E. M. Holmes exhibited and made remarks on some little-known seaweeds, including *Monostroma Blythii* and *Capsosiphon aureolus*, collected at Taymouth, *Oscillaria Corallinæ* from Weymouth, and *Schizothrix lardaica* from Paignton. Mr. Holmes pointed out that *Spermothamnion intricatum* gathered near Swanage showed gradual transition to *S. Turneri*, of which it should henceforth be considered only a vegetative form.—Mr. George Murray exhibited and described the peculiarities of some galls of *Rhodymenia* formed by a crustacean.—Prof. G. B. Howes exhibited a specimen of *Lima hians*, with a byssus "nest" which it had spun in 21 days in a vessel of sea-water in which it had been placed. Although constantly watched by day and night, the act of spinning had not been observed.—On behalf of Mr. J. W. Willis Bund, Mr. Harting exhibited and made some remarks upon a South Pacific Petrel (*Œstrelata torquata*, Macg.), which had been shot in Cardigan Bay in December last.—On behalf of Prof. Martin Duncan, who was unable to be present, Mr. P. W. Sladen exhibited two microscopic preparations of the ambulacral ampullæ of Echini, showing that each ampulla is supplied by one offshoot from the main ambulacral water-vessel.—Mr. Harting exhibited a specimen of the Baltimore Oriole (*Icterus Baltimore*), which had been lately obtained at Balta Sound, Shetland.—A paper was then read by Rev. Prof. Henslow, entitled "A Contribution to the Study of the Relative Effects of Different Parts of the Solar Spectrum on the Assimilation of Plants." The paper was illustrated by diagrams, and a discussion followed, in which the President, Prof. H. Marshall Ward, Dr. D. H. Scott, and others took part.

Paris.

Academy of Sciences, November 10.—M. Hermite in the chair.—New researches upon the synthesis of rubies, by MM. E. Fremy and A. Verneuil (fourth communication). The anthors have succeeded in producing rubies on the large scale, and of greater size than heretofore. The artificial stones are as good as the natural rubies for the purposes of the watchmaker.—Study on the fluor-spar of Quincié, by MM. Henri Becquerel and Henri Moissan. The following conclusions concerning the fluor-spar from this locality, long considered of special interest on account of the peculiar odour it evolves on being broken into fragments, have been formulated in this paper: (1) that the fluor-spar from Quincié contains an occluded gas, which is seen to be disengaged when fragments of the spar are broken under the microscope; (2) that all the reactions furnished by the fluor-spar from Quincié may be explained simply by the presence of a small quantity of free fluorine in the occluded gas.—On the approximate representation of a function by rational fractions, by M. H. Padé.—On the analysis of hypophosphorous, phosphorous, and hypophosphoric acids, by M. L. Amat. These acids or their salts may be analyzed either by means of mercuric chloride or potassium permanganate, provided the conditions given are adhered to. The most precise method is that in which mercuric chloride is employed, but the time required is much greater.—Combinations of mercuric cyanide with salts of cadmium, by M. Raoul Varet. Bodies having the following formulæ have been described—

(1) $HgCy_2$, $CdCy_2$, HgI_2, $7H_2O$.
(2) $2HgCy_2$, $CdBr_2$, $4{\cdot}5H_2O$.
(3) $HgCy_2$, $CdBr_2$, $3H_2O$.
(4) $HgCy_2$, $CdCl_2$, $2H_2O$.

—On the preparation and properties of benzoyl fluoride, by M. E. Guenez.—Synthesis of citric acid, by MM. A. Haller and A. Held.—Experimental study of the *rôle* attributed to lymphatic cells in the protection of the organism against the *Bacillus anthracis*, and in the mechanism of adventitious immunity, by M. C. Phisalix. It is shown that the lymphatic ganglion plays both a mechanical and chemical *rôle*: it is an organ that arrests and considerably modifies the form and virulence of the *Bacillus anthracis*.—Experimental production of white tumours in the rabbit by the inoculation of attenuated cultures of Koch's bacillus into the veins, by MM. J. Courmont and L. Dor. The experiments indicate: (1) primitive local tuberculosis appears to be due to the action of an attenuated tubercular virus; (2) after having penetrated directly into the blood, no effect may be observed for some months; (3) the articular synovials, at least in young subjects, favour the implantation of the attenuated tubercular virus more (but without local traumatism) than the visceral organs.—On the development of *Dondersia banyulensis*, by M. G. Pruvot.—New researches on the spores of *Myxospongial* (structure and development), by M. P. Thélohan.—Observations of Norwegian salmon, by M. J. Kunstler.—The Coleopterous parasites of Acridia: the metamorphoses of Mylabrides, by M. J. Kunckel d'Herculais.—On the means (1) of recognizing sections of felspar parallel to the 010 plane, in thin slabs of rocks; (2) of utilizing their optical properties, by M. A. Michel Lévy.

Amsterdam.

Royal Academy of Sciences, October 25.—Prof. van de Sande Bakhuyzen in the chair.—Mr. van Diesen, having referred to his note of January 27, 1872, concerning the disturbances to which the River Maas is liable in times of flood, explained the plan by which it is proposed that the river shall be directed through a new mouth in the Amer, the present mouth near Woudrichem being closed. This work, which is now in full progress, will diminish the said disturbances. He gave a general view of the details of the scheme, and compared it with the project proposed, in 1822, by General Krayenhoff, whose plan for the separation of the Rivers Waal and Maas will be executed more thoroughly than he intended.

THURSDAY, NOVEMBER 27, 1890.

THE UNITED STATES CENSUS.

WE are surprised that so little attention is being given here to the totals of the United States census which are just being published. There is no more important record in the life of a people than its census. Accounts of progress are impossible without it. In the United States, also, special attention is given to the census, partly because it is a requirement of the Constitution, which assigns representatives to States and districts in accordance with the population figures. Every ten years, in the United States, there is a vast outlay on the business, with which outlay nothing spent in Europe can compare. But now there are loud complaints all over the United States that the record for 1890 is *wrong;* that the population of cities and places has been miscounted grossly. If these complaints are true, the United States might almost as well have had no census at all. All the elaborate work which is to be based on these population figures is rendered useless before it is begun Apart from the direct loss to the United States people themselves, who lose the information about their own affairs the census might have given them, the whole world sustains a loss in being deprived of comparisons of many kinds with so remarkable a progress as that of the United States. Has a colossal blunder, then, been made? and what can be the reason of it?

That there is a huge blunder, or worse, somewhere, appears quite unmistakable. Those who are interested have only to cast their eye over the following table to see that something unusual happened to the 1870 census, and has again happened to the 1890 census :—

Population of the United States, since 1800, and increase in each decennial period.

	Population (in thousands).	Increase. Amount.	Per cent.
1800	5,308	—	—
10	7,239	1,931	36
20	9,634	2,395	33
30	12,866	3,232	33½
40	17,069	4,203	33
50	23,191	6,122	36
60	31,443	8,252	35½
70	38,558	7,115	23
80	50,156	11,598	30
90	62,481	12,325	24½

In all this long period the increase of population in the United States has been at the nearly uniform rate of a *third* every ten years, with the two exceptions of the 1870 census and the 1890 census, in which the increase is respectively 23 and 24½ per cent. only. What can have happened, first between the 1860 census and that of 1870, and next between the census of 1880 and that of 1890, to make the results so different from those of all the other periods?

Now, what happened between 1860 and 1870 is partially explainable. These were the years of the great Civil War, in which privation and disease, with death and injuries on the battle-field, had their thousands and millions of victims. Such causes are well known to check the growth of population. Unfortunately, also, there is another partial explanation. It has been admitted on the highest authority, that of General Walker, who supervised the census of 1880—and the admission is now repeated by the superintendent of the 1890 census—that the figures of the 1870 census were in some States falsified, with the result that in 1880, when the census of that year was taken, an impossible increase of population appeared to have occurred in those States. As far as *amount* is concerned, however, the former explanation has always been understood to be the more serious.

Can any such explanation be given of the small increase between 1880 and 1890? The answer is obvious. There has been no war or the like occurrence since 1880 to check the growth of population. There is absolutely nothing to suggest why the United States population, having increased most rapidly from the beginning of the century down to 1880, excepting during the war decade of 1860–70, should have suddenly had its rate of growth arrested.

More than this, the period between 1880 and 1890 has been one in which, according to past experience, owing to the special magnitude of the immigration, the rate of growth should have been as great as in any of the previous periods. The amount, and proportion to the population at the previous census, of the immigration into the United States since 1820, has been :—

Census period.	Amount.	Proportion to population at the previous census.
1820–30	128,000	1·3 per cent.
1830–40	538,000	4·2 ,,
1840–50	1,427,000	8·4 ,,
1850–60	2,814,000	12·2 ,,
1860–70	2,264,000	7·2 ,,
1870–80	2,707,000	7·0 ,,
1880–90	5,275,000	10·5 ,,

Thus, between 1880 and 1890, as far as the element of immigration is concerned, the growth of population in the Unites States was as much stimulated as in any previous decade, with the single exception of the 1850–60 period. There was absolutely no reason, then, why the rate of growth should fall off between 1880 and 1890, but a special reason why it should not fall off.

When we compare the figures in amount, we are still more bewildered. Between 1870 and 1880, with an immigration of 2,707,000 only, the increase of population is 11,598,000; so that, deducting the immigration, the increase which is due to the excess of births over deaths appears to be 8,891,000. Between 1880 and 1890, with an immigration of 5,275,000, the total increase of population is 12,225,000, and if we deduct the immigration, the increase which is due to the excess of births over deaths appears to be 6,950,000 only! The excess of births over deaths which was nearly 9,000,000 between 1870 and 1880 falls to less than 7,000,000 in the following decade, although the population at starting was 25 per cent. greater in the later than in the earlier decade. Making any reasonable correction for the under estimate in the 1870 census itself, which is now admitted, we still find these figures most startling. Even if we were to increase the population of 1870 to 40,000,000, as the superintendent of the 1890 census now suggests, thus reducing the apparent increase between 1870 and 1880 from about 9,000,000 to about 7,500,000, we should still be confronted by the fact that, starting from a larger population, and with a larger immigration, the excess of births over deaths in 1880–90 would have been from 25 to 30 per cent. more than in the previous decade, or at least 9,500,000, whereas it appears to be under 7,000,000. The figures of the 1890 census are, therefore, quite incredible.

The superintendent of the 1890 census has issued an explanation, which does not, we fear, amount to very much. He makes a great deal of the errors in the 1870 census, which we have already glanced at, and asserts that the rate of growth of population, when proper corrections are made, was much less than 30 per cent. in the 1870–80 period, so that the rate of 24½ per cent. between 1880 and 1890 does not show a great falling off. But while he makes too much of the 1870 errors in amount, he makes no mention at all of the much larger immigration between 1880 and 1890 than in the previous decade, which should have made a difference of at least 3½ per cent. in the rate of growth in favour of the latter as compared with the former period.

A farther explanation is that there is a permanent tendency for the rate of growth of the population of a country like the United States to fall off. But this is not confirmed so far by any figures of a completely trustworthy kind, while the falling off in the rate of growth to be here accounted for is too great and sudden to be explained in such a manner.

The blunder is thus left quite unexplained, and the people of the United States, we may hope, will not fail to see to it. It concerns wider than merely national interests that the blunder should be seen to. For purposes of comparison, every census in the world is thrown out. Looking at the causes of the errors in the 1870 census, viz. an attempt to understate the numbers of the people in Democratic States, and at the special complaints of under-statement which have now come from New York and other Democratic centres, we have altogether too much reason to fear that the cause of the blundering is political. But, whatever the cause may be, it should be stringently looked into.

SPIDERS' WEBS.

American Spiders and their Spinning Work: a Natural History of the Orb-weaving Spiders of the United States, with Special Regard to their Industry and Habits. By Henry C. McCook, D.D. Vol. II. pp. 1–479, with 5 Coloured Plates and 401 Woodcut Figures. (Philadelphia: Allen Lane and Scott, 1890.)

IN a notice of vol. i. of the above work (NATURE, vol. xlii. p. 244), its object and scope were explained. Vol. ii., now before us, fully justifies what was there stated as to the thoroughness with which the available materials on the subject have been brought together from all sources, and for the first time presented to the world as a whole. A similar popular treatment also of this interesting and most important part of the subject is again here observable. Vol. i. was occupied with the snares and web-spinning of orb-weaving and some other spiders, principally in relation to the getting of their livelihood. Vol. ii. treats of these spiders in respect to the propagation of their kind, and web-spinning as subservient to this. Vol. i., in fact, presents us with spiders safely arrived at maturity, and forming their snares and webs with all the diversity and perfection peculiar to each species; while vol. ii. takes them up at that point, and shows them to us in all the different peculiarities pertaining to the performance of the ultimate object of their existence. Naturally, therefore, the volume before us begins (part i., chapter i.), with an account of the sexes in their relation to each other preparatory to actual pairing. This latter and the points arising out of it form the staple of chapters ii. and iii., which complete part i. A certain air of sentimental allusion, which appears to pervade the author's method of presenting this part of his subject, is perhaps merely a matter of taste, and so beyond the province of scientific criticism. It may be, however, that this, while it certainly adds nothing to scientific accuracy or progress, does add to the popularity of the subject, which is evidently throughout the work one of its author's great objects. On the small size of many male spiders compared with their bulky females, Dr. McCook does not appear to accept the views of a former writer upon it, in which it should be observed that the primitive equality in the size of the sexes is by no means implied; the general rule being that the male is the smaller of the two. But if it be granted that the female had a propensity for attacking and devouring the male, those males which happened to be the smallest and most active would be the most likely to escape, and perform the functions of the sex; natural selection would then come in, and operate gradually in the direction of lessening the size of the males. That there are numerous spiders, and groups of spiders, in which the sexes are nearly equal in size, or live in amity together, or in which the males are furnished with some protective armature against the ferocity of the female, proves nothing against the theory of the action of natural selection in lessening the size of the male in such cases as those where a devouring propensity existed and was otherwise unprovided against; for in groups where any approach to equality in size existed and became protective, or where some other protection became developed, there would be no need, in fact no case, for natural selection in the direction of diminished size, there being no advantage to be gained under it. The drift, however, of the author's reasoning on this subject (p. 7) is not very apparent.

Part ii. treats of the "Maternal Industry and Instincts of Spiders"; embracing the formation of cocoons for the reception of their eggs, and the bringing into existence of the young, which naturally leads (part iii.) to the consideration of the life of the young while still engaged in the struggle for existence necessary for the survival of the fittest. The dispersion of spiders on the approach of maturity leads to an account of their method of locomotion on gossamer lines and flakes, completing part iii.

Part iv. enters into the subject of the senses of spiders, and their relation to habit. The structure of the eyes, and their functions are gone into in considerable detail. The remarkable position of these organs in the males of some species—such as *Walckenaera acuminata*, Blackw., in which they are seated near or at the top of a very long slender kind of footstalk—is mentioned; and it is supposed (p. 298) that this might give the male spider an advantage when in search of the female; but, apart from this explanation not being warranted by any known facts as to the habits of the spider, it would seem to be well enough accounted for as the result of excess of vigour or vital force belonging to the stronger or male sex. The action of natural selection would operate here also, indirectly, and these and other similarly excessive developments would only be checked when they tended to become, or became (as in some cases they indeed appear to have nearly become), positively detrimental, or at any rate disadvantageous, to the sex. The senses of spiders—"smell," "hearing," and "touch"—are then gone into. In connection with the sense of "hearing," various stock stories about spiders and the effect of musical sounds upon them are detailed; but such small credit is attached to them as relating facts on which any scientific conclusions can be based, that it would hardly seem to have been worth while to swell an already bulky volume by their repetition. Chapter x. of part iv. ends with the details of the stridulating power of some spiders and its probable purpose. Chapter xi., on the colour, and colour-sense, brings part iv. to a conclusion. The more brilliant colouring and ornamentation of the male spider, in some groups, is accounted for by the preference supposed to be given on the part of the female to males thus ornamented. But it does not appear that this preference is yet proved in any instance as a fact; nor can it be fairly argued that, because sexual excitement often leads the male to display it in curious antics and contortions, it therefore follows that the female is in the least influenced by it; whereas in fact, as she is stated to be (p. 63), the female is generally an unmoved spectator. Doubtless the male frequently succeeds in his purpose after such displays—*post hoc* certainly, *sed non propter hoc*. The author having come to the conclusion that the female prefers the male for his bright colours, we are not surprised to find it argued, conversely, that in those groups where it is the female sex which is the largest and bears the brightest hues, it is the less gaudy male who is helped and influenced in his choice by the increased size and excessive coloration of the female. The argument here also does not appear to have more real weight than in the former case, if even so much. On the subject of adaptation of the colouring of spiders to their surroundings and its beneficial effect, the opinion is expressed that, considering the great exposure to enemies of numbers of brilliantly coloured and conspicuous spiders, no generalization is yet warranted. No weight seems here to be given to the supposition that some of these exposed spiders may be distasteful as food; while it is admitted that many, as those of the genera *Gasteracantha* and *Acrosoma*, are protected by their spiny armature, and, it may be added, by their generally hard integument. The theory of "warning colours" is dismissed as inapplicable to spiders. Adopting the experiments of Sir John Lubbock and Mr. and Mrs. Peckham, spiders are considered to possess a sense of colour; but when we are told that a test case was afforded by a spider whose eyes had been purposely blinded with paraffin, our confidence in the result of these experiments will perhaps be a little shaken; since it is gravely argued from this test case that, because a blind spider exercised no apparent choice of one colour over another, this proves that the apparent preference of a spider before blinding was a true choice, and that there exists a colour-sense in certain spiders. Chapter xii. of part v. is on that most interesting part of natural history in all its departments—resemblance to other objects both inanimate and animate, with the causes and consequences of the resemblance. Space will not permit us to follow the author in the details of this part of his subject. The chapter will be read with pleasure and interest by most observers; but we may perhaps remark that there is at times an apparent tendency to take inability to perceive any resulting advantage from the resemblance as a proof that the resemblance is not the result of natural selection.

Chapter xiii. of part v. treats of the enemies of spiders, and their influence on habit. This subject is, of course, closely connected with protective resemblance; and by no means the least interesting part of this chapter is the account of some truly parasitic spiders—*Mimetus interfector* and others. These take up their abode in the webs of other spiders, and after eating the rightful owner, regale themselves at leisure upon its eggs and young. Part v. ends with chapter xiv., on "Death and its Disguises; Hibernation, and Death feigning." Natural death may be almost said to be an unnatural event in the history of most of the creation, excepting man; but perhaps more frequent instances of it are seen by the entomologist and araneologist, than by other naturalists. Some of our British *Drassidæ*, in the genus *Clubiona* for instance, may often be found sewn up in a nest of leaves drawn together, with their egg-sac, brooding over it, in various stages of lethargy, sometimes so shrivelled and comatose as to be almost incapable of movement. These spiders probably drop to the earth with the opening of the nest for the exit of the young, and at once die when their progeny begin to live. The author gives interesting details of a similar kind in reference to spiders of the family *Epeiridæ* far removed from the *Drassidæ*, and we have also noted it in another family equally remote from both, *Thomisidæ*. "Death feigning" is considered to be perfectly voluntary, though perhaps developed out of an original state of "fright-paralysis"; contrary to the opinion and explanation given by Darwin of this habit. The concluding part of the book, part vi., contains an account of fossil spiders, a subject which, though bearing very little upon the "spinning work of spiders," has a very strong and an increasing interest of its own. It appears to be well treated in the twenty-three pages here devoted to it. We cannot leave this necessarily very incomplete notice of Dr. McCook's bulky volume without drawing especial attention to the numerous (401) woodcuts, and the coloured plates, with which it is so profusely and usefully illustrated. The greater part of these are engraved from the author's own original drawings, and evidence a skill as well as a power of patient observation scarcely equalled in any contemporary work on natural history.

O. P. C.

MR. BASSET'S ELEMENTARY TREATISE ON HYDRODYNAMICS AND SOUND.

An Elementary Treatise on Hydrodynamics and Sound. By A. B. Basset. (Cambridge: Deighton, Bell, and Co. London: George Bell and Sons. 1890.)

WHEN the Senate of the University of Cambridge decided to adopt the suggestion of the Special Board for Mathematics to include the elements of hydrodynamics and the theory of sound among the subjects of Part I. of the Tripos, teachers of these subjects naturally looked to Mr. Basset to provide a text-book that should meet the wants of students preparing for the examination, and he has responded to the demand with great promptitude. The present treatise is designed, he tells us, for those who are reading for this examination and others in which a knowledge of these subjects is required. If the purpose of the book had been different—if, for instance, it had been written as a purely scientific training for hydraulic engineers, or for use in a physical laboratory—it would have had to be conceived in a very different vein. We should have looked for full explanations of elementary concepts, frequent appeals to experiment, constant arithmetical interpretation of the analysis, and a large proportion of physical reasoning. If, however, the book is to be judged by the standard it aims at, it must be regarded as an admirable specimen of an examination book. The propositions are clearly set out in a methodical order. They are isolated from each other as much as possible, and proved individually by the use of appropriate principles. The examples are for the most part well chosen, and calculated to initiate the student into a great variety of the tips and dodges with which the examiners are likely to be familiar; and no more is generally given than would be useful in writing out bookwork and solving problems.

We proceed to a detailed account of the work.

The treatise is divided into two parts, of which the first deals with hydrodynamics, and the second with the theory of sound. In the first part there are five chapters. Chapter i. treats of the kinematics of fluids and of the general equations of motion. We are glad to see that the author has given prominence to the "flux method," and has had the courage to restore the elementary parallelepiped which Prof. Greenhill affects to despise; for the purposes of an elementary treatise the value of this artifice is too great to be lost. Very welcome also is the proof of the important principle at the foot of p. 11, first stated exactly in the larger treatise, vol. ii. p. 234, and apparently due to Prof. Greenhill ("Encyc. Brit.," Art. "Hydromechanics"). We could wish that the theory of the bounding surface had been as fully explained. The same chapter i. contains a short account of sources, doublets, and images, and electric and magnetic analogies are given which add much to the usefulness of these sections.

Chapter ii. treats of the motion of a sphere and of the motion of certain cylinders in an infinite fluid. The descent of the sphere under gravity is very nicely worked out, the usual ambiguity being avoided by explicitly introducing the distance of the centre from a fixed horizontal plane. The resultant pressure on the sphere is calculated, and the equations of motion deduced from Newton's second law. The chapter concludes with an interesting account of the resistance of a liquid to the motion of a spherical pendulum. This chapter contains an exception to the general plan of the work. Mr. Basset appears to write hydrodynamics *con amore*, and cannot always be restrained from trying to teach the student something which he will not be called upon to write out. We refer to his account of recent researches in the theory of the resistance of viscous fluids.

Chapter iii. is occupied with the theory of the motion of a single solid in an infinite liquid. This part of the subject is less elementary than the others which are treated in the book, inasmuch as the machinery of moving axes has to be introduced. The author has cleverly avoided the use of Lagrange's equations and Routh's method of ignoration of co-ordinates, but it must be confessed that it is sometimes a little difficult to see how some of the terms in the equations are obtained by means of the principles invoked. The student may well be puzzled to account for the term $-M'g$ in the equation of motion of the sphere on p. 69. The most interesting problem discussed in the chapter is that of the motion of an elliptic cylinder. Drawings of the path of the centre of gravity in the three cases of oscillation, revolution, and just complete revolution, are given. In the first case, the path looks something like an orthogonal projection of a curve of sines, and the cylinder moves so as to have turned through the maximum angle when the centre is at an inflexion; it then turns back, and the angle described goes through a periodic oscillation while the cylinder moves over a wave-length. In the second case, the path looks like a nodal trochoid, and the cylinder makes one complete revolution in the time taken to pass from a node to the next consecutive node but one. In the third case, the path looks like a nodal cubic with an inflexion at infinity. The cylinder moves from infinity with its major axis initially parallel to the asymptote; at the furthest extremity of the loop it has turned through a right angle, and it then goes off to infinity in the opposite direction, and only turns through two right angles in the whole length of its path. Other interesting things in the chapter are the application of the theory of helicoidal steady motion to explain the necessity of rifling guns, and the theory of the motion of a cylinder in a fluid bounded by a fixed rigid plane, leading to the suggestion of the realization of "action at a distance" by means of fluid pressure.

Chapter iv. is devoted to liquid waves. All the elementary problems are treated very elegantly. "Long waves" are in the first place regarded as a particular case of progressive harmonic waves, and the "exact theory" of long waves in a canal comes afterwards. This seems to us the most natural order. Another point of interest is the discussion of a case of instability, due to Lord Rayleigh. Mr. Basset has done well all through to insist upon the importance of investigations relating to stability.

Chapter v. is occupied with the theory of rectilinear vortices. The vortex line is treated as an ideal limit of a vortex cylinder, and some cases in which the cylinder is of finite section are discussed. We think it unfortunate that in treating the elliptic vortex cylinder the value of the constant D is not given, as it is directly proportional to the circulation; but the student reading the section is certain to take it to be an arbitrary constant. The simplest cases of motion of a straight vortex in a bounded space are treated by the method of images. The chapter concludes with new proofs of Helmholtz's celebrated "laws of vortex motion." A brief account of Sir W. Thomson's theory of "vortex atoms" would have been of interest here.

Part ii. of the treatise deals with the theory of sound, and contains five chapters. The first of these (chapter vi.) is intoductory, and explains the relation of musical notes to the vibrations of bodies, and the connection between sound and the propagation of waves in air. It is admirable rather for conciseness than for completeness of exposition.

Chapter vii. is occupied with the vibrations of strings and membranes, nearly the whole of it being devoted to transverse vibrations of strings. The method of acoustics is adopted, as developed in Lord Rayleigh's treatise. It consists in assuming the motion to be periodic, and dependent upon a function called a normal function, in a series of which arbitrary functions can be expanded. Mr. Basset has changed the nomenclature, so that the "normal co-ordinate" of Lord Rayleigh is here called a "normal function." Is this intentional? The method adopted dispenses with the necessity of proving Fourier's theorem. Other things in this chapter worthy of note are the formation and discussion of the equation of motion for a string subject to viscous resistance and under the action of a periodic force, leading to a particular illustration of the well-known theory of forced vibrations.

Chapter viii. is occupied with the theory of the vibrations of bars. It opens with an account of the stress in a bent bar, and we have here the first hint in an English book on acoustics of any difficulty in that subject. In a footnote Mr. Basset clearly states the nature of the assumption usually made, and further expresses his conviction that it is not rigorously true, describing the character of the change in the equations of motion if a more exact theory were adopted. It is a good thing to have mentioned this. The rest of the chapter is devoted to the lateral vibrations of bars. The differential equations are obtained by the use of the stress equations, the idea of the method of formation being taken from a paper by Dr. Besant, and the frequency equations are given for the various cases of ends supported in different manners. Although, perhaps, a discussion of them may be beyond the purpose of the book, we cannot help thinking that a few numerical results would assist in the comprehension of the subject

The two last chapters deal with the theory of waves in air. Chapter ix. contains the formation of the differential equation of vibrations, and a discussion of the value of the velocity of sound as given by Newton and Laplace's suppositions respectively. To explain the latter an account is given of the thermodynamics of gases, leading to the relation of pressure to density when the changes are isentropic.

Chapter x. contains an account of some of the simpler problems of plane and spherical waves. We find here the theory of the notes in a doubly closed pipe, and a short discussion of the forced vibrations produced by attributing an arbitrary periodic motion to a disk at one end of the pipe. The interest of vibrations in pipes lies rather, as it seems to us, in the cases where the pipe has one or both ends open. Even when these are treated as "loops," something may be done towards a theory of organ pipes. The relation of the notes in a "stopped" to those in an "open" pipe is not even given as an example, nor do we find any account of the interesting problem of reflexion of waves in a pipe at the stopped or open ends. The next subject treated is the reflexion and refraction of plane waves at a surface of separation between two gases; this is very nicely worked out, the equations and conditions being very clearly given. The rest of the chapter is occupied with spherical waves. We have here Lord Rayleigh's solutions for (1) purely radial disturbance within a rigid spherical envelope; (2) the vibrations in a conical pipe; (3) the resistance of the air to the motion of an oscillating sphere, and the theory of the scattering of plane waves by a small sphere. The last problem, as here solved, requires the expansion of the velocity potential in a series of spherical harmonics—the only instance in the book of the use of these functions.

The book is well printed and nicely bound. The few blemishes we have had occasion to notice will not seriously diminish its value, and Mr. Basset is to be congratulated on having produced a work that certainly ought to achieve success. A. E. H. L.

LOWNE ON THE BLOW-FLY.

Anatomy, Physiology, Morphology, and Development of the Blow-fly (Calliphora erythrocephala). Part I. By B. Thompson Lowne, F.R.C.S., F.L.S., &c. (London: R. H. Porter, 1890.)

MR. LOWNE'S new work on the blow-fly, of which Part I. has just appeared, requires the serious attention of all who occupy themselves with insect anatomy. It contains the results of a diligent and protracted inquiry, and will teach even specialists a good deal which they did not know before.

Mr. Lowne has written before on this subject. His earlier book (1870) on the blow-fly was the manual of what we may now call a past generation of insect-anatomists, who studied it zealously, and, we fear, often got hopelessly puzzled with its many difficult passages. The present publication is not a new edition, but a totally new work, and the author has only thought it worth while to mention his earlier memoir quite casually in one or two places. The interval of twenty years has enabled Mr. Lowne to make great advances in the knowledge of his subject, and his old treatise on the blow-fly may now cease to be read.

This increase of knowledge is due to laborious microscopic investigation, and to a lengthy, though not exhaustive, study of a literature which is copious, technical, and very largely German. The student has to thank the painstaking author for many new facts, and also for a good deal of information, which, though not new, was previously accessible only to specialists.

Perhaps the most interesting remarks which we have found in Part I. relate to the imaginal disks (it would be better to call them imaginal folds), those curious inward growths of the larval epidermis from which nearly the whole body of the fly is ultimately fashioned. Mr. Lowne's account should be carefully examined by those who have hitherto been content with text-book information, or the descriptions of Weismann, which, original and brilliant as they were, required rectification on a number of special points. We can look forward to a discussion of these imaginal folds far more interesting, and at the same time simpler, than any that present knowledge has produced. Such a type as Corethra (which, by the way, is misquoted as Chironomus in the note to p. 77) shows a slight telescoping of the imaginal antenna within the larval head. Other types, as yet imperfectly described, exhibit deeper and more complex invaginations, while the Muscidæ form the extreme term of the series. At this moment we want above all *comparative* studies, and till they are supplied, minute descriptions of highly special cases are hardly intelligible. Few biologists seem to be aware of the interesting research which lies open to any competent student in a well-selected series of Dipterous larvæ and pupæ. It will ultimately be necessary to include other insect-orders, for imaginal folds are not peculiar to Diptera. Many Lepidoptera are instructive in this connection. Pieris, for example, as J. Dewitz (*Biol. Centralblatt*, Bd. iii. p. 582) points out, exhibits that connection between the sutures of the clypeus and the antennary folds which the author (quoting Mr. Hammond) has noticed on p. 43. The subject is not sufficiently worked out for popular treatment, and the beginner who takes up Mr. Lowne's account of the development of the fly has many a hard nut to crack.

The new work contains many interesting particulars concerning the life-history and minute structure of the blow-fly; there are not a few useful figures, and the bibliographical references are tolerably extensive. If the succeeding parts are equally full of matter, the treatise will make a really considerable addition to our knowledge.

Nevertheless there are some faults to be pointed out. The arrangement of the matter is not always convenient or luminous; see, for example, the place (p. 12) chosen for the definition of an insect and the definition of morphology. Now and then an ill-considered remark, perhaps having no close connection with the subject in hand, distracts or misleads the reader. Why should the author go out of his way to speak of mammals, birds, and reptiles as "separate and divergent genetic series" (p. 26), a proposition by no means so evident that it can be thrown in as a passing illustration! Surely Mr. Lowne, by thinking twice, would have saved his readers from puzzling over that strange remark (p. 7) that in all insects (this is apparently the sense) there is no cœlom or "distinct continuous body-cavity."

We shall await with much curiosity the promised proof of the hepatic function of the Malpighian tubules. Meanwhile we can only wonder in what sense the author uses the word *hepatic*. We shall also be glad to learn the reasons for believing in a "metenteron," as defined on p. 17.

No one interested in insect anatomy is likely to adopt all Mr. Lowne's views, but no such person can hesitate to admit that he offers us a substantial contribution to his favourite subject.

L. C. M.

OUR BOOK SHELF.

A Treatise on the Diseases of the Sheep; being a Manual of Ovine Pathology especially adapted for the use of Veterinary Practitioners and Students. By John Henry Steel. (London and New York: Longmans, Green, and Co., 1890.)

SHEEP and their diseases have had but little attention from the veterinary profession, and consequently this work, just published by Mr. J. H. Steel, one of the most astute and successful veterinary practitioners and teachers of the present day, must be looked upon as the result of an important step in the right direction. Though we admit the author's ability and the probable usefulness of the book, yet the most conspicuous feature connected with it is the evidence which it gives of how very little of a sound, practical, and useful nature is known by scientific men in relation to sheep. No claim is made to originality in the subject-matter produced, and indebtedness to the various authorities quoted is freely acknowledged. There is, however, a distinct want of discrimination between those who are the leading authorities on certain subjects and those who are not. One who could write the three names, Walley, Williams, and Gamgee, in the order presented, shows he has no regard for precedence in virtue of merit. Gamgee in his day was perhaps the greatest genius who had ever adorned the veterinary profession, and Williams is unquestionably the most successful living author of veterinary works of a high order. Errors of an extraordinary kind appear where the writer, who is not himself familiar with the subject, attempts to enlarge upon the statements of others from whom he quotes; for example, in writing of the tick, ked, or fag (*Melophagus ovinus*), he says "the animal buries its head and proboscis in the skin, and once fixed hangs on for months. It is nimble and active, and sometimes as large as a horse-bean." Any entomologist familiar with sheep cannot fail to see that the author has mistaken the grass-tick (*Ixodes*) for the sheep-tick (*Melophagus*), which belongs to a different genus, and has confounded the habits of the two creatures in an extraordinary manner. Apart from errors of this kind the work is far from complete, but if due care were taken to correct mistakes and to consult as additional references such recent works of a superior kind as "The Animal Parasites of Sheep," by Dr. Cooper Curtice, published at Washington by the United States Government during the present year, the second edition might be made a most serviceable, interesting, and valuable volume.

Wild Beasts and their Ways. By Sir Samuel W. Baker, F.R.S. Two Vols. (London: Macmillan and Co., 1890.)

NO one who has read any of Sir Samuel Baker's books of travel will need to be told that he has all the instincts and aptitudes which, under favourable conditions, make a man an eminent sportsman. He is, however, much more than a sportsman; as he himself says, he has never hunted without a keen sense of enjoyment in studying the habits of the animals pursued. In the present work he records some of the experiences he has had in various parts of the world, and students of natural history will find in his narrative much that cannot fail to interest them. The book is not, of course, in the strictest sense scientific; but it has points of contact with science, and these will make it as welcome to zoologists as it is sure to be, for other reasons, to general readers. Sir Samuel confines himself to wild animals which he himself has had opportunities of watching, so that all the incidents and scenes he brings before us have that kind of freshness and vividness which can belong only to descriptions that embody the results of direct personal observation. The work is admirably illustrated by reproductions of drawings prepared by Mr. Dixon.

Properties of Matter. By P. G. Tait. Second Edition. (London: Adam and Charles Black, 1890.)

THIS is a revised and considerably extended edition, and the author has paid special attention to points in connection with which difficulties had been found. Among the more important additions are the results of some of M. Amagat's splendid and hitherto unpublished work relating to the compression of liquids exposed to enormous pressures. This in itself, when completed, will, as the author remarks, "form a singularly interesting and practically new branch of the subject."

Our Fancy Pigeons. By George Ure. Cheap and Enlarged Edition. (London: Elliot Stock, 1890.)

THE title of this book does not give quite an accurate idea of the contents, for in the first part there is a good deal about fishing and things in general, and the third is a collection of "rambling ornithological notes." In the second part, however, the author deals systematically with the pouter and other "high-class breeds," and offers some remarks on minor varieties of fancy pigeons. Mr. Ure is a lively writer, and his facts and opinions are presented as the results of long-continued personal study and experiment.

Alexis and His Flowers. By Beatrix F. Cresswell. (London: T. Fisher Unwin, 1891.)

THIS pretty volume is intended for boys and girls, and, as it is brightly written, ought to be read by them with pleasure. It contains much quaint and interesting "flower-lore."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Romanes on Physiological Selection.

IN his two latest articles dealing with this subject, Dr. Romanes has made certain statements as to my position in regard to it which call for a brief notice on my part.

In his original paper, and in the summary of it published in NATURE, Dr. Romanes adduced variations in regard to fertility and sterility as the fundamental fact in physiological selection. A few quotations will show this. He says: "It becomes almost impossible to doubt that the primary specific distinction (meaning sterility) is, as a general rule, the primordial distinction" (NATURE, vol. xxxiv. p. 339). Again, he enforces this as against Darwin's view that sterility was a consequence or concomitant of other differences, as follows: "My theory, on the other hand, inverts this order, and supposes the primary distinction to be likewise (in most cases) the primordial distinction" (*l.c.*, p. 363). This is very clear, but to show that he limited the term "physiological selection" to the results supposed to arise from this phenomenon, we have his reply to Mr. Galton, who urged a fact also dwelt upon by Darwin—the psychological disinclination to mate between many varieties—as an important factor in the differentiation of species: "Now I have fully recognized this principle as one amongst several others which is accessory to, although independent of, physiological selection" (*l.c.*, p. 407). A little further on he again states his fundamental fact thus: "If my theory is true, it must follow, as Mr. Galton says, that such unions would be more or less sterile, and, as this sterility is itself the only variation which my theory supposes to have arisen *in the first instance*, *ex hypothesi* we can have no means of observing whether or not the individuals which present this variation 'consort with outsiders,' or with those individuals which do not present it" (*l.c.*, p. 407). As if to leave no possible doubt as to the special point of his new theory, he again enforces it in the following passage: "And forasmuch as the sexual separation arises only by way of a variation locally affecting the reproductive system, when the variation is first sexually separated, it will in all other respects resemble its parent stock, and so be able to compete with it on equal terms" (*l.c.*, p. 408).

Now surely all this makes it absolutely clear that Dr. Romanes's theory of physiological selection, so far as it had any originality, was founded on the supposition of sterility-variation alone, arising in an otherwise undifferentiated species; and he claimed that such variations "cannot escape the preserving agency of physiological selection," and that "physiological selection must be quite as vigilant as natural selection, and it seizes upon the comparatively unuseful variation of sterility with even more certainty than natural selection can seize upon any useful variations" (*l.c.*, p. 364).

These last statements, by the truth of which alone the use of the term "selection" can be justified, I showed by two carefully considered cases to be absolutely unfounded, and the exact opposite of what must really occur (*l.c.*, p. 467; and "Darwinism," p. 182). Having thus proved that "physiological selection," in the only form claimed by Dr. Romanes as original, does not exist, and that the only modes by which degrees of sterility between distinct species can arise are those discussed or suggested by Darwin himself, with the addition of the possible action of natural selection in increasing incipient sterility between slightly differentiated forms, will it be believed that I am accused of having appropriated the theory of physiological selection without acknowledgment! In the *Nineteenth Century* (May 1890, p. 831), Dr. Romanes says of me: "He presents an alternative theory to explain the same class of facts. Yet this theory is, purely and simply, without any modification whatsoever, a restatement of the first principles of physiological selection, as these were originally stated by myself." And now, in the October issue of an American magazine, *The Monist*, he has an article entitled "Mr. A. R. Wallace on Physiological Selection," in which the original main point, of sterility-variations alone leading to and constituting "physiological selection," is almost entirely ignored, and the various modes by which isolation is produced between incipient species or in which infertility arises in correlation with other divergent characters, are all claimed as forming part of the theory of physiological selection. He quotes from "Darwinism" my exposition of the effects of partial infertility arising between "two varieties in process of adaptation to somewhat different modes of life within the same area," to show "how unequivocal and complete is Mr. Wallace's adoption of our theory" (*The Monist*, No. 1, p. 11). "Our" refers to Mr. Gulick, who is taken into partnership by Dr. Romanes. And again he speaks of "the peculiar position to which he has eventually gravitated with reference to my views—professing hostility on the one hand, while reproducing them as original on the other" (*l.c.*, p. 19).

I have here confined myself to showing, by Dr. Romanes's own repeated and emphatic statements, what was the essential and original theory to which he gave the name of "physiological selection." The whole of this special doctrine I have argued against as unsound, because, on close examination, it proves to be quite inadequate to produce any such effects as are claimed for it. Whether I was right or wrong in doing so, I did, as a matter of fact, and do still, wholly reject this fundamental and essential part of the theory—the only part which had even a *primâ facie* claim to originality. I also totally reject the two subsidiary doctrines on which Dr. Romanes lays great stress as adjuncts of his theory—that of the inutility of a large proportion of specific characters, and that of the power of isolation alone "without the aid of natural selection" to produce new species; while, so far as I know, the only points in which I agree with him are those in which we both make use of Darwin's facts and adopt Darwin's explanation of them. Yet, notwithstanding this rejection of all that is special in his teachings, Dr. Romanes has the hardihood to assert that I claim them as my own; that I merely restate his theory "purely and simply, without any modification whatsoever"; and that my adoption of his theory "is unequivocal and complete."

I leave it to others to characterize these extraordinary statements in the terms that fitly apply to them.

ALFRED R. WALLACE.

Attractive Characters in Fungi.

I NOTE in your issue of November 6 (p. 9), Mr. Straton mentions the fact of the common mushroom spores being unproductive until they have passed through an animal host, naming horse, sheep, and oxen, but it appears to me it must be rendered equally fertile after passing through the larvæ of beetles, flies, &c., else how could nurserymen supply spawn with mycelium ready for generation? It is possible, therefore, that though larger animals act very often as hosts to mushroom spores, insects are mainly responsible for their reproduction. The soft spongy nature presents but little resistance to the ovipositor, and most mushrooms if examined in a state of decomposition will be found perforated by maggots, the larvæ of Diptera and Coleoptera.

It is possible that a sustained high temperature is necessary to the first stage of development in fungi, which is admirably attained in the living host, but it is probably immaterial whether the mycelium is developed on the excreta of mammal or insect. Heat is evidently a great factor even in the second stage of germination, as the so-called "spawn" will remain dormant for a long period unless it is applied. I well remember a peculiar case in point. A wild hill-top covered with gorse and bracken was to be taken into cultivation; it had been unturfed, the turves and gorse being piled in heaps and burned on the ground (many acres in extent) now ready for the plough. It was in the month of August. While these heaps were still smouldering, there came two days of heavy rain; immediately after, sprang up like magic an immense crop of mushrooms, chiefly close to the ash-heaps. They were unusually large, and the tops were very brown—scarcely to be distinguished from the bare earth they grew on.

These germs must have been gradually collecting under the turf for years, beaten in by the weather, the moss slowly growing over and hiding them from the air and heat. The removal of the turf exposed them, when, forced by the extraordinary heat of the burning heaps, they suddenly sprang into existence. In after years, when the ground was under cultivation, they were seen no more, for the reason, probably, that when the plant-life was all destroyed, a great part of the insect-life went with it, and thus the means of propagation was lost.

Biarritz, November 23. R. HAIG THOMAS.

P.S.—I have never actually seen cattle or horses eat mushrooms, but that goats certainly eat some kinds of fungi I can state positively, as last year, in Norway, I had an opportunity of personally observing the fact. A party of us were walking through the pine forest; one of the peasants was leading a goat down the mountain from a *sæter* to his farm below. My companions called me to look at the goat, which had stopped in the pathway, and was greedily nibbling at a large piece of sponge-like fungus, such as one finds commonly in the woods. She speedily ate it all up. We expressed some surprise, but the peasants told us goats were very fond of and often eat fungi.—R. H. T.

AS stated by Mr. Cooke (NATURE, November 20, p. 57), there is an apparent contradiction between the impossibility of finding out some process of "impregnation" previous to the formation of the spores in Hymenomycetes, and, on the other hand, the occurrence of forms suspected to be "hybrids."

A very remarkable statement in De Bary ("Morphol. u. Physiol. der Pilze," § 1, p. 2), however, may perhaps afford a clue to the mystery, viz. the occurrence of amalgamations between hyphæ originally produced from distinct spores. Might not such a process as this possibly lead to "hybrids," if those spores belonged to distinct species? W.

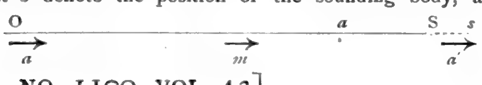
Freiburg, Badenia, November 22.

I WAS shown the other day, in a wine cellar, completely excluding light and fresh air, a remarkably beautiful growth of fungus, covering the wall and floor, to a depth of 4 inches in places, and suggesting cotton-wool in form and colour. When taken up and pressed, it turned brown and emitted the characteristic fungus smell. I should be glad to learn the name, and whether the pure white of the fungus is due to the total exclusion from light. M. H. M.

Doppler's Principle.

THIS subject was referred to in NATURE some months ago, but, although the question is comparatively simple, there is one point of some importance which was not then brought out and to which I have never seen any reference. The change in pitch is, of course, due to the change in the rate at which the cycles of disturbance which constitute the wave-motion fall upon the ear. To determine this change of rate, it is necessary to consider (1) the space occupied by each cycle; (2) the relative velocity of the wave-motion and the observer. Consideration (1) is connected with the velocity of the source of sound, and if wave-length be defined as the shortest distance between two vibrating particles in the same phase, then the space occupied by each cycle may be called the wave-length. If, however, wave-length be defined as the distance which the wave-motion travels through the medium during the "period" of vibration of the sounding body, then the wave-length so defined is unaffected by the motion of the sounding body. It is in connection with this point that there is generally some ambiguity in the usual terms of explanation.

Let S denote the position of the sounding body, and O



that of the observer. If a denote the velocity of the observer, a' the velocity of the sounding body, m that of the medium, and v the velocity of sound, then during the "period" of the vibration of the sounding body the disturbance travels, *through the medium*, a distance $\frac{v}{n}$, where n is the frequency of the vibration. During this period, however, S is displaced to s, a distance $\frac{a'}{n}$; and, owing to the motion of the medium, the disturbance originally starting from S, although traversing a length $\frac{v}{n}$ through the medium, only reaches a point a at a distance $\frac{v-m}{n}$ from S. The distance, $sa = \frac{v+a'-m}{n}$, is thus the actual distance between two particles in the same phase, or gives the *effective* wave-length.

The velocity of the motion through the medium is v, and therefore its velocity relative to O is given by $v+a-m$. Hence, in one second, the number of effective wave-lengths which fall upon the ear is expressed by

$$n' = \frac{v+a-m}{v+a'-m}n.$$

That is, the pitch of the note heard at O is given by n'. This is the formula given by Prof. Everett in NATURE, vol. xlii. p. 81.

Cambridge, November 18. R. W. STEWART.

The Comb of the Hive-Bee.

IN a recent article the Bishop of Carlisle puts forward, as conclusive objections to the perfecting of the cells in the comb of the hive-bee by natural selection: (1) the fact that other kinds of bees continue; (2) that the sterile workers cannot transmit favourable variations.

But (1) other bees, however inferior in comb-making, may have advantages in other respects; thus the humble-bee can reach the nectar of flowers that are not accessible to the common hive-bee. (2) Favourable variations in the workers would presumably or possibly appear in the further swarms thrown off from the hive or home from which these proceeded; and further, seeing that the workers are really females, the queens in the swarms so thrown off may inherit and transmit the favourable tendency. WM. KNIGHT.

Savile Club, 107 Piccadilly, W., November 22.

A Swallow's Terrace?

MR. A. G. VERNON HARCOURT has just shown me, in his boat-house at Cowley Grange, a specimen of swallow's architecture unlike anything I have seen or heard of. The nest, which is itself normal, is placed at the end of a small beam extending from the top of the door to the angle of the building. This beam is about two feet and a quarter in length, and four inches broad. The nest is at the end next the door; the whole of the rest of the surface of the beam is occupied with an adjunct to the nest, which looks as if it had been meant for the family to perch and roost on. It consists, like the nest, of a foundation of dried mud, carefully covered with dry grass; and it is obvious that much care and pains were spent on its construction. Its length (excluding the nest) is nearly two feet.

Mr. Harcourt thinks that the nest was built late last summer, but he did not notice it then, or discover the use of this curious terrace. Can any of your readers parallel or explain it?

W. WARDE FOWLER.

Lincoln College, Oxford, November 20.

Araucaria Cones.

IN answer to the Duke of Argyll's inquiry respecting the coning of the *Araucaria imbricata* in the British Isles, I beg to state that there have been, within my own cognizance, several instances of the same during the last thirty or forty years in this country, notably at Maresfield in Sussex, at Bicton in Devonshire, and especially at Chatsworth. The famous avenue of them at Chatsworth frequently produced cones during the last ten years of the trees' existence prior to 1860, when the memorable severe frost on Christmas Eve completely destroyed the whole avenue, despite the artificial screens of branches of evergreen shrubs that had been annually adopted for their protection from severe winterly weather, so I have been informed by a trustworthy eye-witness, who also stated that the cones produced by the trees in question always proved seedless. The trees, curiously, were all females, and had no opportunity of impregnation. In further reference to the diœcious character of this genus of Conifers, I am informed that the Maresfield trees, as indicated, failed to produce fructiferous cones until males were planted within suitable proximity to them. Pertaining, further, to the sexuality of the Araucaria, I believe that a distinguishing character exists in the size of the foliage, that of the cone-bearer being considerably the larger.

Bearing on the sudden fruition of the Inveraray tree, it may be interesting to relate a parallel case, which occurred upwards of twenty years ago, when I was residing in the neighbourhood of Stratford-on-Avon. A fine specimen of that beautiful Spanish silver fir (*Picea Pinsapo*), on one windy day, became prostrate, and exposed, to my surprise, the greater portion of its main roots in a fungous, diseased condition, thus solving the problem why the tree had for the last few years assumed a stunted growth. Fortunately, however, as two or three of the main roots on one side of the tree remained intact, I resolved to raise it to its former position, after having cut away every vestige of diseased or broken roots; which was successfully accomplished by the aid of a stout rope and pulley-block, and a dozen able men. Subsequently the tree did not appear to suffer materially from the trying ordeal it had been subjected to, and my anticipations of its resuscitation were shortly afterwards justified by a healthy renewed growth, and the interesting appearance, in the course of two or three years, of a crop of beautiful cones, specimens of which I exhibited at one of the Royal Horticultural meetings in 1869, and for which a "Special Certificate of Merit" was awarded. Evidently the cause of this abnormal fruition—as in the case of the Inveraray Araucaria—was owing to arrested growth. In conclusion, I may add that I failed to discover the real cause of the decay of the Picea's roots, but attributed it to something unsuitable in the almost impervious damp subsoil, the fungous condition being only consequential.

WILLIAM GARDINER.

Harborne, Birmingham, November 15.

P.S.—Respecting the sexuality of the Araucaria, it would be instructive as well as interesting could any of your correspondents define any comparative specific character possessed by the plants, such, for instance, as the foliage or general habit, when in their earlier life, and whereby they may be distinguished.—W. G.

EARLY this summer the Araucarias of large size around Terregles House, near Dumfries, were in fruit. Many of the shed cones were lying at the base of the plants. Several years ago I saw a fine Araucaria in fruit in the manse garden, Colvend, Kirkcudbrightshire; but learned from the incumbent that the sight was a rare one. About the middle and end of October, this year, we had numerous trees of the mountain ash from which the leaves had fallen, but which stood glittering, laden with red berries. Clouds of fieldfares arrived, at first noisy and shy, perching on the tops of larch-trees. They devoured these berries, and, getting bolder, invaded my garden, and clustered on a mountain ash in such numbers that there could not be less than 200 at one time. At two visits of one hour each, in one day, every berry disappeared from that tree. Now the flocks of fieldfares are no longer visible, and the berries of the hawthorn and other wild fruit do not seem to attract them, while not a berry of the mountain ash could be picked up for many miles.

JAMES SHAW.

Dumfriesshire.

THE GENESIS OF TROPICAL CYCLONES.

ACCORDING to the views of Dr. Hann, as explained in a previous number of this journal (Nov. 6, p. 15) the storms of the temperate zone originate, not in the convective ascent of warm damp air (an explanation, however, which he appears to admit in the case of tornadoes), but in great vortical movements of the upper air-currents, which commence over the equator as the anti-trades, and set continuously towards the poles, being gradually diverted eastwards in consequence of the earth's rotation. Owing to the spherical form of the earth's surface, these currents become irregularly congested as they necessarily converge on reaching higher latitudes, and thus give rise to anticyclones, or tracts of excessive accumulation and pressure, and to cyclonic vortices in the intervals. Admitting this view as at least highly probable, the question now to be considered is how far similar conditions hold good in low latitudes. Do the cyclones of the tropical zone originate in like manner, or are they not rather primarily due to the conditions of the lower atmosphere, to the production and condensation of vapour over a calm region, and the creation of an upcast current?

In the first place, it is to be observed that in low latitudes those causes which impede the even flow of the upper currents are at a minimum. Their tendency to congestion must vary as the contraction of the degrees of longitude in successive parallels of latitude; and whereas between latitude 40 and 50, for instance, this amounts to 16 per cent. of the length of the degree, and between 50 and 60 to 22 per cent., between 5° and 15 it is little more than 3 per cent. Accordingly, the non-periodic oscillations of the barometer, which, in Europe, frequently amount to an inch in the course of a day or two as cyclones and anticyclones successively sweep past, in the latitude of Madras (13° N.) rarely much exceed a tenth of an inch in the whole course of a month. But cyclones originate certainly as low down as latitude 8°, and instances have been recorded in 7° and even 6°.[1]

On the other hand, the supposed alternative cause, viz. the production and condensation of vapour, is at a maximum in low latitudes, and the facts recorded by Eliot, Pedler, and others who have traced out the early history of Bay of Bengal cyclones, go to show that their formation is determined by the inrush of a saturated current from the equatorial sea, and that this inrush is preceded by at least one or two days of disturbed squally weather in the birthplace of the storm. Moreover, the evident relations of these storms to the features of the terrestrial surface, always in the early stages of their existence, and frequently after they have been maturely developed, seem to admit of no other conclusion than that they are, primarily at least, phenomena of the lower atmospheric strata, even though at a later period the vortical movement may be imparted to the greatly elevated anti-trade, and so be carried forward into higher latitudes. And lastly, as Dr Hann has himself shown, the temperature test, which he rightly appeals to as crucial, and which in his hands has led to the overthrow of the condensation theory of extra-tropical storms, does not fail when applied (as far as the data admit of) to the case of tropical cyclones. On each of these points some further elucidation is necessary.

First, as regards the place of their origin: and in these remarks I shall restrict myself to the storms of the Bay of Bengal and the adjacent Indian continent, which have been more closely studied than those of other tropical seas. A chart given by Mr. Eliot in his recently published "Hand-book of Cyclonic Storms in the Bay of Bengal" shows that they are generated with about equal frequency in all parts of the bay betweeen N. latitudes 8° and 18°. Between latitude 18° and the Bengal coast they are much more frequent, though generally of less intensity. But they are formed very rarely indeed over any part of the Indian peninsula. I can remember but one such case during an experience of many years' daily study of the weather charts. And although they originate somewhat more frequently in Lower Bengal during the height of the monsoon, even these instances are rare in comparison with those of storms generated at the head of the bay during the same season. With but few exceptions, therefore, they are formed only over the sea, and these exceptions are nearly all restricted to the low plain immediately north of the bay. If the original impulse were a vortical movement of the higher atmosphere, it

[1] See the list of storms in Appendix II. to the "Weather and Climates of India."

would be difficult to account for this practical limitation of the storm cradle to the surface of the bay; whereas on the alternative assumption the reason is obvious.

Next, with respect to season and antecedent circumstances. The fierce and destructive cyclones which accompany the changes of the monsoons are generated chiefly in the south of the bay in the spring and late autumn, and further north at the beginning of the summer and in the earlier autumn months; while during the height of the summer monsoon, the less severe storms, which I have elsewhere distinguished as "cyclonic storms," are formed in the extreme north of the bay, and occasionally, though rarely, over the plains of Bengal; in which case they never attain to any great strength. Over the storm cradle at the outset, and everywhere to the north of it, the atmosphere is calm and sultry, or moved only by light variable winds; and at the change of the monsoons, when storms are formed far out in the bay, the atmospheric pressure is nearly uniform all over the bay, and even over the land there are only those slight differences, it may be either of excess or defect, that are due to the normal distribution of the season. Cyclone formation seems to be but little if at all affected by the barometric condition of the atmosphere over the Indian continent. But storms always originate somewhere beyond the northern limit of that saturated equatorial atmosphere which is itself fed by the southern trade winds, and is the reservoir from which is drawn the rainy summer monsoon. In this direction the pressure is always somewhat higher, but until the cyclone has formed, the gradients are gentle.

Thus the average birthplace of storms advances and recedes with the northern limit of the southern monsoon, being always situated beyond it in the region of nearly uniform and relatively low pressure, calms, or light and variable winds, which extends over a greater or less area beyond that limit.

Over the cradle of a storm, the formation of a vortex is always preceded by disturbed squally weather, during which the barometer falls slightly over the disturbed area. In most instances this lasts for two or three days, sometimes longer, and during this period there is but little rain around the coasts of the bay. As this preliminary occurrence of squally weather is a point of some importance, I will quote a passage describing it more fully from Mr. Eliot's recent work:—"The history of all cyclones in the bay shows that they are invariably preceded for longer or shorter periods by unsettled squally weather, and that during this period the air over a considerable portion of the bay is gradually given a rapid rotatory motion about a definite centre. During the preliminary period of change from slightly unsettled and threatening weather to the formation of a storm more or less dangerous to shipping, one of the most important and striking points is the increase in the number and strength of the squalls which are an invariable feature in cyclonic storms from the very earliest stages. First of all the squalls are comparatively light, and are separated by longish intervals of fine weather, and light variable or steady winds, according to the time of year. They become more frequent, and come down more fiercely and strongly, with the gradual development of the storm. The area of unsettled and squally weather also extends in all directions, and usually most slowly to the north and west. If the unsettled weather advances beyond this stage (which it does not necessarily do), it is shown most clearly by the wind directions over the area of the squalls. The winds always settle down into those which invariably occur over an area of barometric depression or cyclonic circulation, or, in other words, are changed into the cyclonic winds of indraught to a central area of low barometer and heavy rain. As soon as the wind directions indicate that a definite centre of wind convergence has been formed in the bay, it is also found that the centre never remains in the same position for any considerable interval of time, but that it moves or advances in some direction between north-east and west, with velocities which not only differ very considerably in different storms, but also at different stages of the same storm."

Such being the facts, as gathered from the detailed study of a great number of storms, their most probable interpretation seems to be somewhat as follows. It may be taken as an established fact that rain is, practically in all cases, the result of the dynamic cooling of ascending air, and that whenever the rain is accompanied by squalls this ascent is irregular and spasmodic. If so, the weather that precedes a cyclonic circulation, as described in the foregoing paragraph, indicates that over a previously calm area the lower atmosphere gradually acquires a spasmodic ascending movement, at first sporadic but gradually becoming concentrated as the influx of the surrounding atmosphere impresses a spiral movement on the general mass. With the influx of the saturated current from the south, this action is greatly accelerated, and the vortical movement which has originated in the lower atmosphere is imparted to the higher atmospheric current, which carries it forwards, at first slowly, and then with increased velocity, as the movement gradually extends to the higher and more rapidly moving current of the general atmospheric circulation.[1] Were the seat of the original disturbance in the bosom of the upper current, it is difficult to see why the disturbed condition of the lower atmosphere should remain stationary during the incubation of the storm, or why it should exist sometimes for two or three days in anticipation of the spiral circulation, which, on this hypothesis, is the determining impulse of the whole phenomenon.

I am not aware that anyone has as yet made a special study of the circumstances under which the storms of the temperate zone originate. Some of them doubtless enter this zone from the tropics. But as the result of a somewhat cursory examination of the Atlantic charts published by the Meteorological Council, others appear to be formed very rapidly either as secondary eddies in the circulation of the North Atlantic atmosphere around Iceland, or in the V-shaped depressions between two neighbouring anticyclones. In neither case does there appear to be that prolonged incubation that characterizes the Bay of Bengal storms; notwithstanding that heat and vapour must be far less active agents in high than in low latitudes. Indeed, this consideration seems to add support to Prof. Hann's views, while it also tends to strengthen the probability that tropical and extra-tropical storms arise from a different class of actions.

Further evidence that tropical cyclones are originally and chiefly phenomena of the lower atmosphere is afforded by the fact that even the most violent storms are often broken up by hills of very moderate height. Notably was this the case with the destructive Backerganj cyclone of November 1, 1876, a very large and violent storm, which nevertheless broke up on reaching the low hills of Tipperah; and perhaps a majority of the cyclones that cross the Coromandel coast from the bay are dissipated by the ghats and hill-groups of the Carnatic, few of which exceed 5000 feet in height. In these cases, a disturbed state of the atmosphere indicated by heavy rain outlasts the cyclone sometimes for two or three days, but the strongly-marked vortical circulation disappears.

It has been suggested to me by Prof. Hann that even

[1] This assumes, of course, that the poleward current of the general circulation exists normally above the calms and variable currents of the monsoons, and such is equally the assumption of the opposite hypothesis. The observations on the progress of the Krakatão dust-cloud indicate only a very rapid westerly current, circulating around the globe in the equatorial zone in August. Those of the movements of high clouds at Calcutta and Allahabad, at a much less elevation than the Krakatão dust-cloud, indicate very variable directions in the summer and autumn, but chiefly southerly at Calcutta, and west or south-west almost exclusively at both stations during the remainder of the year. See the tables in the "Weather and Climates of India," pp. 60, 61.

if the severe cyclones of the transitional periods of the monsoons arise in the way I have above indicated, the milder but more lasting "cyclonic storms" of July and August which are generated in the extreme north of the bay, and which often traverse a great part or the whole of Central and North-Western India before they break up, may nevertheless be formed in the same manner as those of the temperate zone. But this seems to me extremely improbable. With the single exception of the place of their origin, the circumstances of their formation are essentially identical with those of the former class. Moreover, the track which they almost invariably follow seems to be determined by the distribution of the monsoon currents, being along the trough of low pressure which lies between the easterly and westerly branches of the monsoon of Northern India. Although the belt of broken hilly ground running across Central India is generally traversed by the storm vortex, the winds which mainly feed it from the bay have a clear sweep up the great Gangetic plain, and those from the Bombay coast, after surmounting the ghats, have a tolerably unimpeded course across the Deccan plateau, whereas in such cases as the Backerganj cyclone, the whole broad range of the Arakan Yoma, from 5000 to 7000 feet in height, presents an obstacle to the single feeding current from the Bay of Bengal.

I come lastly to the crucial test of temperature—to the question, namely, whether the mean temperature of the air-column in a tropical cyclone is such as to render it specifically lighter than the surrounding atmosphere, and therefore such as to promote an ascending movement. We have indeed in this case no high-level observations to appeal to, such as are furnished to Dr. Hann by the Alpine and other mountain observatories for the storms of the temperate zone. But Dr. Hann has made a rough computation which enables us to bring it fairly to the test, and which in the case of European storms was found to give a result entirely justified by observation. In a paper published in the September number of the *Meteorologische Zeitschrift* he has computed the temperatures of the air-column over a tropical cyclone at different elevations, on the assumption of adiabatic cooling, and has compared these with the average normal temperatures of the atmosphere at the same elevations as deduced from the observations of Newera Eliya, Dodabetta, and Antisana. As the result, he finds that the mean temperature of the former is probably about 2° C. higher than that of the latter, and therefore such as to produce an upward movement of the cyclonic atmosphere, with an acceleration equal to about $\frac{1}{300}$ of the force of gravity. It may indeed be somewhat greater than this, since in his computation Dr. Hann has assumed a temperature of 28° C. or 82°·4 F., and a relative humidity of only 80 per cent. for the atmosphere of the cyclone at sea-level. In point of fact, observation shows that in a cyclone in the south of the bay the temperature at the sea-level is 79° or 80°, but that the air is saturated, or close upon saturation. Making this correction of the data, the mean temperature of the cyclonic air-column will be about 3° C. higher than that of a normal atmosphere, equivalent to an accelerating force of $\frac{1}{200}$ of gravity.

From every point of view, then, whether we regard the place and circumstances of their origin, their behaviour after formation, their physical constitution, or the relative activity of the causes supposed to be concerned in their production, the conclusion seems irresistible that tropical cyclones originate in a manner quite different from that ascribed to the storms of the temperate zone; that they are in their early stages a disturbance of the lower atmosphere; and that the primary impulse is given by the ascent and condensation of vapour.

These remarks apply only to the "cyclones" of the beginning and end of the summer monsoon, and the "cyclonic storms" of the summer months. The storms that traverse Northern India in the winter and early spring, which always travel eastward, and but very rarely descend within the tropic, are of quite a different character, and may not improbably originate in the manner suggested by Prof. Hann.

HENRY F. BLANFORD.

THE DE MORGAN MEDAL.[1]

IN 1869 Lord Rayleigh commenced the long series of papers and memoirs in Mixed Mathematics, which the Council had in view in making the award, with an article (*Philosophical Magazine*, vol. xxxviii., third series) "On some Electro-magnetic Phenomena considered in connexion with the Dynamical Theory," founded on Clerk-Maxwell's celebrated "Dynamical Theory of the Electro-magnetic Field" (Phil. Trans., 1865), the subject being "Examples of Electro-magnetic Problems illustrated by comparison with their Mechanical Analogues." I may add, to complete the key-note, thus struck, of Lord Rayleigh's scientific career, that these theoretical results were followed up in the next year by an account of "An Electro-magnetic Experiment," viz. the magnetizing effect of an induced current as dependent on the self- and mutual inductions of the circuits—an early instance of the author's practice of making theory and experiment, or concrete example, illustrate one another. This combination of experimental with mathematical skill and fertility of resource has been conspicuous in Lord Rayleigh's later memoirs on the "Determination of the Ohm and B.A. Unit of Resistance in Absolute Measure" (Roy. Soc. Proc., vol. xxxiv., and Phil. Trans., vol. clxxiii., 1882.)

Confining myself to those earlier memoirs and papers by Lord Rayleigh in which mathematical investigation predominates, the next which calls for notice is one of considerable length, "On $\int_0^1 Q_n Q_{n'} d\mu$ ($Q_n Q_{n'}$ being Laplace's coefficients of orders n, n'), with an Application to the Theory of Radiation" (Phil. Trans., 1870); in which, instead of the two Q's being multiplied together and integration then effected, the flank of the difficulty is ably turned and the object attained with comparative ease. The mathematical results are illustrated by their application to the problem of "finding the stationary condition when a uniform sphere is exposed to radiation from infinitely distant surrounding bodies."

"A Memoir on the Theory of Resonance" (Phil. Trans., 1871), is the first of Lord Rayleigh's numerous essays in the mathematical theory of sound, which were preliminary, or have been a sequel, to his well-known Treatise, of which the two volumes appeared successively in 1877 and 1878.

The subject of the Memoir is an investigation of air-waves (of the fundamental note) in hollow spaces, whose three dimensions are small in comparison with the wave-length, and which communicate with the atmosphere by necks similarly limited. The theory is shown to be applicable to cases of multiple resonance, as when two or more such hollow spaces are connected by necks and communicate with the external air by necks.

The question of the calculation of c, a factor or coefficient occurring in some of the differential equations, is treated in a noteworthy manner, suggested by the remark that, if the air were replaced by uniform conducting matter of unit specific conducting power, and the sides of the vessel by insulators, c would be the measure of electric conductivity between the interior of the vessel and external space, "an analogy freely availed of, . . .

[1] Address to the London Mathematical Society on the occasion of the presentation of the De Morgan Medal to Lord Rayleigh, November 13, 1890, by the President, J. J. Walker, F.R.S.

much circumlocution being thereby avoided on account of the greater completeness of electrical phraseology."

Having joined our Society in 1871, Lord Rayleigh commenced that series of communications in Applied Mathematics, by which our Proceedings have almost every year since been enriched, with a paper in Physical Optics, "On Verdet's Explanation of Coronas" (vol. iii. p. 267), in which a fallacy of reasoning in his mathematical work is pointed out, but its disappearance in the result explained.[1]

This is the first of many important papers evincing the critical manner in which Lord Rayleigh studies the work of his predecessors or contemporaries, while sympathetically and appreciatingly recognizing the value of their contributions to the progress of Physical Science.

To the fourth volume of our Proceedings was contributed an important triad of papers:—

(1) "On the Vibrations of a Gas contained within a Rigid Spherical Envelope," a problem referred to in the Memoir on Resonance, in which the author indicated the only case of the vibration of air within a closed vessel which had prior to that time been completely worked out, the motion being assumed to be irrotational. The solutions of the differential equations are expressed in terms of Harmonic Functions; and, incidentally, interesting theorems in Operations are proved, if in Laplace's Coefficients μ is replaced by the first or second power of the Operative symbol $1 - d/dy$, the Operand being $1/y$.

I would suggest to those having leisure and taste for such a research the possibility of these theorems being generalized for any positive integral power of the Operator.

(2) The second paper, "On the Disturbance produced by a Spherical Obstacle on Waves of Sound," begins with a series of mathematical lemmas of great interest: the expansion of the velocity potential in a harmonic series, with special consideration of the case of its being finite at the poles, and an independent solution of the case of plane waves; a method leading to an expression in terms of Bessel's Functions of fractional order being explained and applied. A comparison of the two results gives a relation of great elegance between a Laplace's Function of order n and a Bessel's Function of order $n + \frac{1}{2}$.

In an Appendix, the expansion of the Velocity Potential for spherical waves is worked out.

Intimately connected with this second of the three papers are two which appeared in the *Philosophical Magazine* for April and June 1871: "On Light from the Sky, its Polarization and Colour," and "On the Scattering of Light by Small Particles," discussed mathematically. The latter paper, setting out with supposing both density and rigidity of the media variable, shows that there can be no direction in the plane perpendicular to the incident ray in which the scattered light vanishes. Hence, either there is no difference of rigidity (the supposition of the former paper), and the vibrations are normal to the plane of polarization; or no difference of density, and the vibrations are parallel to the plane of polarization—which latter alternative is then disproved.[2]

(3) The third of the triad of papers referred to bears the title, "Some General Theorems relating to Vibrations," with which the Author "had lately become acquainted during the preparation of a work on Acoustics." The first principle proved is that "the natural periods of a conservative system, vibrating freely about a configuration of stable equilibrium, fulfil the stationary condition."

Some applications of the principle are pointed out, and in illustration of one of these—the approximate calculation of a complicated system, but slightly different from one of a simpler nature—the problem of the transverse motion of a stretched string of slightly unequal longitudinal density is worked out. Another instructive example is that of the tones of a square plate when the type of vibration is such that the nodal lines are central and parallel to the edges, the tone being then gravest, and that in which the diagonals are the nodal lines. The former case is here discussed mathematically for the first time, and Chladni's experimental results shown to be confirmed. An important remark on the *possibility* of expansion by Fourier's Theorem, Laplace's Series, or Bessel's Functions, in a large number of cases being inferred from physical considerations, is added.

The second principle is that forces which vary as the component velocities (absolute or relative) of the vibratory motions of the parts of the system may be advantageously treated by the method of Virtual Velocities. The investigation leads to the introduction of a function, F (the "Dissipation Function"), which, like the Kinetic and Potential Energy Functions, is a positive quadratic function of the co-ordinates, and represents the rate at which Energy is dissipated. Its application in the fourth chapter of the Author's great work on Sound will at once occur to those acquainted with it. Finally, a law of reciprocity of a very general character is established, relating to the interchangeability of forces and motions of any two types.

The subject of Reciprocal Theorems in Dynamics has been recently (January 12, 1888) treated in our Proceedings by Prof. Lamb, led thereto by a reciprocal theorem, proved by von Helmholtz in a paper "On Least Action" (*Crelle*, vol. c.), which seems much the same as Lord Rayleigh's, if somewhat more generally expressed.

Arising out of this theorem is "A Statical Theorem," communicated by Lord Rayleigh to the *Philosophical Magazine* (vol. xlviii., 1874), referring to a reciprocal property of a system capable of vibrating, with or without dissipation, if displaced from a position of stable equilibrium. The application of the principle in Acoustics (introduced into the "Theory of Sound") formed the subject of a communication to the Royal Society (Proceedings, xxv., 1876).

In this enumeration of some of Lord Rayleigh's earlier papers should be included two of a pure mathematical character on Bessel's Functions, viz. (1) "Notes" thereon, published in the May number of the *Philosophical Magazine*, 1872, in which their great utility in questions of the conduction of heat or electricity, or of a hydrodynamical nature, with conditions to be satisfied by circular, spherical, and cylindrical surfaces, is pointed out. It is needless to remark how constantly these Functions have since been pressed into service in such cases.

(2) "On the Relation between the Functions of Laplace and Bessel," communicated to our Society (Proceedings, vol. ix., January 1878), in which the Function of zero order is shown to be the limit of Legendre's (P_μ), and the general Function that of an "Associated" Function of Laplace, where n becomes infinite, but n sin . angle cos μ remains finite. A linear relation among three consecutive Associated Functions, which in the limit becomes the well-known one among three consecutive Bessel's Functions, established by their discoverer, follows.

In connexion with the two papers just noticed, allusion may be made to a "Note," also contributed to our Proceedings (June 11, 1874) "On the Numerical Calculation of the Roots of Fluctuating Functions," pointing out how the difficulty of evaluating them when the argument is neither very small nor great may sometimes be met; the

[1] What regretful thoughts are stirred up by the recollection that Clerk-Maxwell joined in a discussion of this paper, commenced by Sir W. Thomson! From 1871 to his death, Prof. Maxwell was a frequent participator in, as well as contributor to, our meetings. "Quis desiderio . . . !"

[2] The volumes of the *Philosophical Magazine* for the same year (1871) contain two other optical papers of great interest:—

"On Double Refraction" (vol. xli.), in which the mathematical treatment of the subject, by supposing density to be a function of the direction of vibration, leads to the replacing Fresnel's ellipsoid by its polar reciprocal. Reference is made to Stokes's Report.

"On Reflexion of Light from Transparent Matter" (vol. xlii.), the object of which is "to see how far the facts might be accounted for by the different hypotheses which have been made as to the condition of the æther in transparent matter."

method, though not limited to, having arisen out of, and being exemplified by, Bessel's Functions.

I pass now to Lord Rayleigh's work subsequent to the award of the medal in 1887, which the Council are enjoined by the rules for their guidance to take into special consideration. In the *Philosophical Magazine* for August 1887 there is a paper "On the Maintenance of Vibrations by Forces of Double Frequency," a sequel to that "On Maintained Vibrations," *ibid.*, April 1883. To this subject Lord Rayleigh tells us his attention had been recalled by Mr. Glaisher's Address to the Royal Astronomical Society in the preceding February, in which he had given an interesting account of the treatment of mathematically similar questions, occurring in the Lunar Theory, to those herein considered, by Mr. Hill, published in the *Acta Mathematica* of the preceding year. The appearance of a "dissipative term" in the equation of motion of the vibrating body prevents it being treated as a special case of Hill's similar equation in the motion of the Lunar Perigee. The results are expressed by determinants, and one of the recent papers of Dr. Muir is referred to, on the relations of the special class of determinants involved to continued fractions. Applications to the case of the vibrations of a laminated medium, in which the mechanical properties are periodic functions of one of the co-ordinates—a problem connected with the colours of thin plates; and to the problem of the stationary vibrations of a string of variable density fixed at two points, follow.

In our Proceedings for November 1887, will be found a paper "On the Stability or Instability of certain Fluid Motions," forming a sequel to a former paper on the same subject in our eleventh volume (1880), to which Lord Rayleigh's attention had been re-directed by a recent work of Sir W. Thomson's. In this the subject is treated with greater generality.

In the following year Lord Rayleigh communicated to our June meeting a short but interesting investigation, "On Point, Line, and Plane Sources of Sound," giving rise to a definite integral the connection of which with Bessel's Functions is worked out by Lipschitz's method (*Crelle*, 1859), referred to in the paper of 1877 on Bessel's Functions.

In the Royal Society Proceedings, December 13, will be found a paper in which Mr. Love's objections (Phil. Trans., 1888, A., p. 545), to the line of argument followed in Lord Rayleigh's paper in the thirteenth volume of our Proceedings (1881), "On the Infinitesimal Bending of Surfaces of Revolution," are replied to with great fulness. The interest aroused by these discussions will be well remembered by those who followed them; and allusion to them has since been frequently made at our meetings.

The same memoir by Mr. Love drew forth another mathematical investigation by Lord Rayleigh (Roy. Soc. Proc., February 26, 1889), "On the Free Vibrations of an Infinitely Long Cylindrical Shell."

At our meeting, April 11, 1889, a paper by Lord Rayleigh was read, "On the Free Vibrations of an Infinite Plate of Homogeneous Isotropic Elastic Matter," a particular case of which "On Waves Propagated along the Plane Surface of an Elastic Solid" had been investigated in a communication to our November meeting of the year 1885.

In the before-mentioned years (1888–89), Lord Rayleigh contributed four important papers in the mathematics of Physical Optics to the *Philosophical Magazine*.

(1) "On the Reflexion of Light at a Twin Plane of a Crystal" (*Phil. Mag.*, September 1888). For the calculation of reflexion at the surface between twin crystals, the electric theory of Clerk Maxwell is found to be the only one satisfying the conditions essential to success—as capable of explaining at once Fresnel's laws of double refraction and those governing the intensity of reflexion when light passes from one isotropic medium to another. Starting with Maxwell's equations connecting the components of the electric displacement and current, magnetic force, electro-magnetic momentum and force, and taking the plane of transition as $x = 0$, Fresnel's tangent formula for isotropic reflexion is obtained; then his law of velocity for propagation in a crystal.

Reflexion at a twin plane is then limited to the cases of the plane of incidence, being (1) coincident with, (2) perpendicular to, the plane of symmetry. In the former case it is shown that the ratio of the amplitudes of the reflected and incident light is equal to the difference of two expressions proved to be equal, whether the vibrations are parallel or perpendicular to the plane of incidence, and no light is reflected whether the incident light be natural or plane-polarized, or elliptically polarized.

The values of the parameters which multiply the exponents in the two reflected waves in the second case are then worked out. Finally, particular cases of these general results are discussed.

(2) "On Interference of Light radiated from Moving Molecules" (*Phil. Mag.*, vol. xxvii. 1889) combats Ebert's conclusions by showing that the maximum admissible retardation is 4·5 times greater than assumed by him (*Wied. Annalen*), whence the width of the spectral lines should be much greater than found, which would involve a blow at the dynamical theory of gases.

(3) "On Complete Radiation at a Given Temperature" (*ib.*), founded on Gouy's "Theory of Irregular Impulses," investigates what type of similar impulses would by their aggregation represent complete radiation. The probability of various amplitudes depends on principles explained in an article in the *Philosophical Magazine*, August 1880, "On the Resultant of a Large Number of Vibrations of same Pitch and Arbitrary Phase." The form of impulse (familiar in the Theory of Errors)—

$$\phi(x) = \text{exponent } (-c^2x^2),$$

which is resolved into harmonic components by Fourier's Theorem, is discussed.

(4) "On Achromatic Interference Bands" (*Phil. Mag.*, vol. xxviii., August and September 1889). A development of notice of in the article "Wave Theory" ("Enc. Brit.," 1888), founded on Cauchy's law of dispersion; with a reference to Mascart, "Achromatism of Interference" (*Comptes Rendus*, March 1889).

These abstracts, imperfect as they are, may serve to convey to those who have not closely followed his work some idea of the great variety of subjects in Mixed Mathematics discussed and advanced by Lord Rayleigh, and on which that distinguished reputation in these domains is founded, their recognition of which the Council of the London Mathematical Society desire to mark by the present award of the De Morgan Medal.

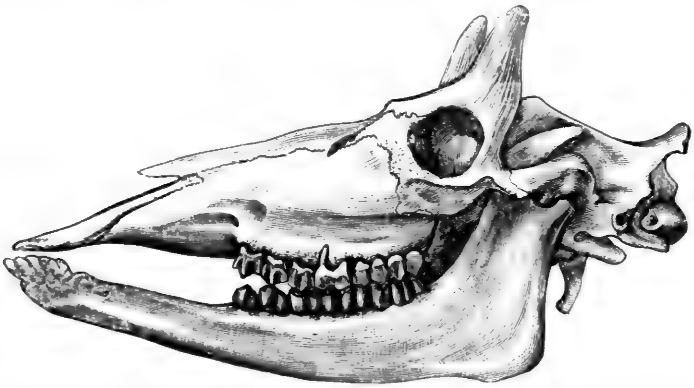
A NEW FOSSIL MAMMALIAN FAUNA.

THE trustees of the British Museum have recently added to the collection at South Kensington a large series of fossil remains of mammals purchased from Prof. C. J. Forsyth-Major, which are of especial interest from several distinct points of view. These remains were obtained within the last two or three years by Prof. Forsyth-Major from a Tertiary deposit in Samos—an island in the Turkish Archipelago, lying immediately opposite the town of Ephesus, and to the south-south-west of Smyrna. This deposit, which has been discovered only quite recently, appears to be absolutely full of the bones of mammals; and in this respect it agrees with the contemporary deposits of the celebrated Pikermi ravine near Athens, the wonderful mammalian fauna of which has been fully made known to us by the labours and writings of Prof. Albert Gaudry, of the Paris Museum, and other palæontologists.

The deposits at Samos have, however, one great advantage over those of Pikermi. Thus, in the latter locality the rock in which the bones are embedded is stained of a brownish-red colour, and very frequently adheres so closely to the bones that they cannot be properly cleaned from matrix; whereas in the case of Samos the rock is of a buffish-white, and can be completely removed from the specimens. This whitish colour of the Samos bones renders them peculiarly attractive objects in a museum; and the contrast between the white bones and the pale-brown of the enamel of the teeth in the magnificent series of skulls now displayed in the Museum is very striking. So well preserved, indeed, are these specimens that many of the skulls are almost as well suited for precise anatomical comparison as those of existing species.

The number of specimens from these deposits acquired by the Museum is no less than 533; the whole of these, with the exception of one bone of a bird, belonging to mammals. As another collection of at least equal extent has been acquired by the Museum at Geneva, the importance of this newly discovered fossil fauna may be readily estimated.

The discovery of this ossiferous deposit, taken in conjunction with that of the equivalent beds at Maragha, in Persia, which were brought to the notice of the scientific world only a few years ago, indicates that there is still hope of much further knowledge of the Tertiary mammalian fauna being eventually obtained by the full exploration of regions lying beyond the European area. As we have already mentioned, the Samos deposits are the equivalents in point of time with those of Pikermi in Attica, and of Maragha in Persia; this identification resting upon the general similarity of the fauna of the three areas, although each locality has some peculiar types not known in the others. The researches of Mr. W. T. Blanford and others have shown that we must assign a Pliocene age to the deposits at Pikermi. And with our present knowledge, the Pikermi fauna may now be traced from Baltavar in Hungary, through Greece, thence to Samos, Persia, Baluchistan, the Punjab, and so to the Siwalik Hills of Northern India, the mammalian fauna of which was the first to be brought to light through the classic labours of Falconer and Cautley. From this fauna, which forms a belt in the regions surrounding the whole of the north-eastern frontier of Africa, it is now pretty certain that the modern mammalian fauna of that continent was derived; and it is noteworthy that the fauna of Samos, and still more that of the Siwaliks, contains the greater number of forms most closely allied to those of Africa. In Pikermi and Samos no true elephants occur, but in the Siwaliks elephants more or less closely allied to the existing African and Indian species are abundantly represented.



Profile view of the skull of *Samotherium*, from the Pliocene of Samos. Much reduced. (From "Guide to British Museum.")

Among the mammals discovered at Samos, a large number are identical with those occurring at Pikermi. Thus, the well-known three-toed horse (*Hipparion*) is especially common in both localities. The rhinoceroses and mastodons likewise appear to have been, in most cases at least, specifically the same. Again, many of the antelopes found at Pikermi, some of which are allied to the African oryx and others to the koodoo, reappear at Samos. A large ruminant from Samos, as yet undescribed, but to which the provisional name *Criotherium* has been applied, appears, however, to be an antelope totally unlike any existing form. In this remarkable animal the horns are set on the extreme vertex of the skull, as in the hartebeest, the gnu, and the ox, but are extremely short, tightly twisted, and bent right in front of the forehead, in a manner totally unlike that found in any existing antelope.

Perhaps, however, the most remarkable of the new mammals discovered at Samos is the large ruminant for which the name *Samotherium* has been proposed. Of the skull of this creature we are enabled, by the courtesy of Dr. Woodward, to give a figure. It will be seen from this figure that the general proportions and contour of the skull are very similar to those of the giraffe; and the molar teeth are practically indistinguishable from those of the latter. The remarkable feature of this skull is, however, the presence of a pair of upright horn-cores, situated immediately over the eyes, and inseparably connected with the frontal bones, of which indeed, as in the antelopes, they form mere projections. This condition is very different from that obtaining in the giraffe, in which, it need hardly be said, the so-called horns are short bony processes, covered with skin in the living condition, and entirely distinct from the frontal bones. The horn-cores of the samothere are, indeed, very similar to those of certain Pikermi antelopes, and were, in all probability, sheathed in horn in the living animal. This ruminant appears, therefore, to indicate a close genetic connection between the giraffes and the antelopes; and since the giraffe itself is very closely allied to the deer, while the extinct Indian sivathere exhibits many points of affinity with the giraffe, but appears to have had deer-like antlers which were never shed, we see how little importance can really be attached to horns and antlers as indicative of want of affinity, or the reverse, between their respective owners. Indeed, there can now be but little doubt that deer, giraffes, prongbucks, and antelopes, are all descended from a common stock; the intermediate and annectant types having mostly died out, although the evidence of their former existence is now slowly but surely accumulating.

The only other mammals calling for especial notice are a species of aard-vark (*Orycteropus*) and a pangolin. The aard-varks, it need scarcely be said, are now entirely confined to Africa and Syria, and the occurrence of an extinct species at Samos may indicate that this group of animals originally reached Africa from the north-east. The fossil pangolin is very considerably larger than any of the existing species, and has been referred to an extinct genus. Since no fossil pangolin has been found in any European deposits, the occurrence of this extinct type is of some interest.

Lastly, we must not omit to mention that the deposits at Samos have also yielded remains of an extinct ostrich, although this species is unrepresented in the collection acquired by the British Museum. The African ostrich is known to have ranged into Persia and Baluchistan within the historic period, and since the genus also occurs fossil in the above-mentioned Siwalik deposits of Northern India, the evidence of its former existence in Samos shows that it once inhabited the whole of that extensive belt of country flanking the north-eastern frontier of Africa, which seems, as we have already mentioned, to have been the original home of the modern Ethiopian fauna.

In conclusion, we venture to express the hope that means will ere long be found by which this magnificent collection of fossil remains will be described and illustrated in a manner worthy of its importance and interest.

R. L.

NOTES.

WE learn that the Weather Service of the United States hitherto under the direction of the Chief Signal Officer, is to be transferred to the Agricultural Department after July 1, 1891. A chief will be appointed at a salary of 4500 dollars a year. The present Signal Corps will be discharged from the army, and will thereafter serve as civilians.

THE first *conversazione* for the season of the Royal Microscopical Society will be held in the Society's rooms, 20 Hanover Square, on the evening of Monday, December 1.

ON Friday last, a marble bust of William Symington was unveiled in the west wing of the Museum of Science and Art, Edinburgh, by Sir William Thomson, who said that Symington was the real discoverer and the practical originator of the steamboat. It was interesting to note that Symington exhibited before the Professors of Edinburgh University a model of a carriage to be moved on the public roads by the power of steam. In 1803, Symington constructed a steamer which took in tow two laden sloops, each 70 tons burden, on the Forth and Clyde Canal. The unveiling of the bust took place amidst loud cheering. Sir R. Murdoch Smith, on behalf of the Museum authorities, accepted the custody of the bust. Amongst those present at the ceremony was Mrs. Dickie, Glasgow, a granddaughter of Symington. The bust is by D. W. Stevenson, R.S.A.

M. TCHIHATCHEF, whose death we lately recorded, left 100,000 francs to the Paris Academy of Sciences, to provide prizes for naturalists who have made noteworthy Asiatic researches.

SOMEWHAT late we learn that Dr. José Jéronimo Friana died at Paris on October 31. The cause of his death is not stated, but the fact that a daughter died in the same house within three days of her father's death points to an epidemic. Dr. Friana was a native of New Granada, born in 1828, and previous to his coming to Europe he was attached to a Survey Commission, and made a collection of more than 5000 species of plants. About the year 1860 he came to Europe with his family, and never returned to his native country. The principal object of his visit to Europe was to determine his plants and prepare a Flora of New Granada. For this purpose he resided partly in Paris and partly at Kew, and spent some years working out his collections. In conjunction with the late Prof. J. E. Planchon, he commenced publishing a "Prodromus Floræ Novæ Granatensis"; but this fell through, partly, we believe, in consequence of a lack of funds, partly in consequence of Dr. Friana's time being occupied by consular and medical duties. For many years he resided wholly in Paris, and filled the position of Consul-General of the Republic of Colombia. Always hoping to be able to resume his favourite botanical pursuit, he kept his large collections at his residence. Among his published botanical work is a monograph of the Melastomaceæ, which appeared in the Transactions of the Linnean Society, and "Nouvelles Études sur les Quinquinas," containing *facsimiles* of Mutis's original drawings. The author visited Madrid, and studied the materials collected by Mutis. Apart from his scientific attainments, Dr. Friana was much loved for his extreme amiability.

HORTICULTURE has sustained a severe and almost irreparable loss in the sudden and unexpected death of Mr. Shirley Hibberd, which we recorded last week. An enthusiastic horticulturist, an accomplished writer, and a fluent and clever speaker, Shirley Hibberd occupied a position that it will be difficult to refill. He was sixty-five years of age, and for more than half that period he has been a constant figure at, and has taken a leading part in, the principal Shows and Congresses in connection with gardening and garden-botany. For upwards of thirty years he was editor of the *Gardener's Magazine*, and he was also the author of many little treatises of considerable literary merit. At the recent Chrysanthemum Show of the National Society of Chrysanthemum Growers, held at the Aquarium, Shirley Hibberd was the most prominent man, both in the lecture-room and as a speaker at the banquet which took place on the Thursday preceding his death. Indeed, it is supposed that he caught a chill in the conference-room, and, bronchitis supervening, the fatal result speedily followed.

IN the Reports on the progress and condition of the Royal Gardens, Kew, from 1862 onwards, there are many useful notes respecting economic and other plants. An index to these notes has just been issued, and will be welcomed by all who have preserved copies of the Reports. The work appears as Appendix III. of the *Kew Bulletin*. In this excellent periodical, to which we have often referred, are now published all notes that may be too detailed for the Annual Report on economic products and plants, to which the attention of the staff of the Royal Gardens has been drawn in the course of ordinary correspondence, or which have been made the subject of particular study at Kew. The preface to the new index concludes with the following statement:—"The *Bulletin*, of which three volumes are already published, and the fourth is in course of publication, may be looked upon as furnishing in a detailed and timely form the special information formerly included in the Annual Reports, but which a necessary economy of space precluded being treated at the length which is possible in the pages of the *Bulletin*. It may be added that the *Bulletin* is published monthly by Her Majesty's Stationery Office, and it may be obtained from Messrs. Eyre and Spottiswoode directly, or through any bookseller."

FROM January 1, 1891, the *Globus* will be edited by Dr. Richard Andree, of Heidelberg, by whose father the journal was established nearly 30 years ago.

THE Council of the University College of North Wales has just purchased for the College library the well-known collection of books belonging to Mr. E. Watkin, of Manchester (formerly of Pwllheli). It consists of upwards of 10,000 volumes, many of which are works relating to botany, chemistry, geology, and other departments of science.

THE recent fire in University College, Toronto, postponed the equipment of the psychological laboratory which Prof. J. Mark Baldwin had in view; but in the plans for the new buildings more ample accommodations are secured. The new laboratory is to be in the restored building in a retired portion of the first floor, immediately over the rooms of the physical department. It will comprise two communicating working rooms, each 16 by 21 feet, a professor's private room, to be used also as a special psychological library under charge of a fellow or instructor, and a dark room available from the resources of the physical laboratory. The first two rooms will be separated by a hall from the latter two. This part of the building will be ready for occupation, it is hoped, in the course of the next academic year. The equipment, apparatus, &c., may be delayed in consequence of the present severe tax upon the resources of the University, but special researches will be prosecuted with the aid of adapted apparatus lent from the very complete collections of the departments of Physics and Biology.

WE learn from the American papers that the provisions of the McKinley Tariff Bill include an exemption of much importance to those engaged in teaching. It permits Universities, Colleges, &c., not only to import books for the institution free of duty, but also for any teacher connected with the institution. All works in languages other than English have been placed upon the free list.

THE efforts which have been made to open commercial communication between England and the heart of Siberia by way of the Arctic Seas have at last been successful. A correspondent of the *Times*, who signs himself, "One who knows all about it," explains the circumstances connected with this remarkable triumph of skill and energy. Two ships and a tug for river work were despatched from London at the end of July and beginning of August. Owing to north-easterly winds the Kara Sea was exceptionally full of ice, so that the ships were detained for some days among ice-floes. Nevertheless, in 39 days the ships and tug reached Karaoul, 160 miles up the Yenissei, without accident. They remained there 19 days, and took 26 days to return. They were thus only 84 days, or two months and 23 days, away from the London Docks. At Karaoul they met the river expedition, which "returned safe to Yenisseisk a few days ago, and is now landing and warehousing there the valuable cargo sent out from England." The same correspondent points out that the real *crux* of the expedition lay in the 160 miles of estuary between Golcheka, at the mouth of the Yenissei, and Karaoul, at the head of the estuary, which the Russian Government had assigned as the port of discharge. Last year the *Labrador* would not ascend to Karaoul, because Captain Wiggins thought there would not be water enough to take him there, and had no steam-launch to enable him to feel his way up. On the other hand, the river ship did not dare to descend because of the gales that then prevailed. This year it was discovered that through the entire estuary there was a channel with sufficient water for ships of any draught, and the ships proceeded up the river to their destination without hindrance. It is unfortunate that Captain Wiggins was accidentally prevented from completing the work with which his name has been so intimately associated, but it was he who showed the way, and to him, more than to anyone, belongs the honour of having provided this new outlet for British commerce. That it may become an outlet of the highest importance is the conviction of no less an authority than Baron Nordenskiöld. In a letter congratulating the promoters of the undertaking, he says:—"I am persuaded that its success will once be regarded as an event rivalling in importance the return to Portugal of the first fleet loaded with merchandise from India. Siberia surpasses the North American continent as to the extent of cultivable soil. The Siberian forests are the largest in the world. Its mineral resources are immense, its climate, excepting the *tundra* and the northernmost forest region, healthy, and as favourable for culture of cereals as any part of Europe." He goes so far as to say that the future of Siberia may be "comparable to the stupendous development which we at present see in the New World."

AT the meeting of the Royal Botanic Society on Saturday, many interesting plants, tropical fruits, &c., grown in the Society's gardens, were exhibited, and the economic value of several were explained by Prof. Bentley, who also noticed a specimen of the fly Agaric on the table from Somerset, presented by Dr. Prior, as containing a very poisonous alkaloid. In some North European countries, where it is common, it is said to be used to increase the intoxicating qualities of liquor. Its name is due to the fact that an infusion in milk is used to poison flies.

PROF. LANGLEY and his assistant, Mr. Very, have been carrying on researches relating to the so-called phosphorescent light of certain insects. They lately brought the subject before the New York Academy of Sciences, and in *Insect Life* (vol. iii., 3) some account of their results is given. The insect principally used in the experiments was the large Cuban firefly (*Pyrophorous noctilucus*). The total radiant heat from the light of one of these insects (heat representing waste) was compared with that transmitted by glass from the nearly non-luminous Bunsen flame, the luminosity from which was very much fainter than that from the insect. The most accurate observations prove that the insect light is accompanied by approximately one four-hundreth part of the heat which is ordinarily associated with the radiation of flames of the luminous quality of those experimented with. Thus Nature produces this cheapest light at about one four-hundredth part of the cost of the energy which is expended in the candle flame, and at but an insignificant fraction of the cost of the electric light, which is the most economic light which has yet been devised. "Finally," the author concludes, "there seems to be no reason why we are forbidden to hope that we may yet discover a method (since such a one certainly exists and is in use on a small scale) of obtaining an enormously greater result than we now do from our present ordinary means for producing light."

THE Division of Ornithology and Mammalogy of the Department of Agriculture of the United States has recently published a Report by Dr. C. Hart Merriam on the fauna and flora of the San Francisco mountain-region of Arizona, in which views are enunciated with regard to the areas of animal and vegetable life on the North American continent different from those usually held. He maintains that there are but two primary life-areas in North America—a northern (boreal) and a southern (subtropical) area, both extending completely across the continent, and sending off long interpenetrating areas; and that the theory commonly accepted by naturalists, viz. that of three life-areas, the Eastern, Central, and Western Provinces, must be abandoned. He further recognizes seven minor life-zones in the San Francisco mountain region, four of boreal, and three of subtropical or mixed origin, the four boreal zones being correlated with corresponding zones in the north and east.

PROF. ALFRED KIRCHOFF, of Halle, contributes to the *Saale Zeitung* an article on "the anxiety with which even scientific men of repute looked forward to the autumn meeting of the International Conference on Degree Measurement, which was lately held at Freiburg." According to an abstract given by the *Times*, Prof. Kirchoff says it had been reported that a series of simultaneous observations, carried on at Berlin, Strasburg, and Prague, went to show that a decrease in latitude was in process, at least in Middle Europe, and further reports from other Observatories showed that a similar phenomenon had been noted in other places in Europe. This implied an alteration in the direction of the earth's axis. That is, the poles and equator, latitude and longitude, are not, as usually assumed, practically fixed data, but are liable to the general terrestrial law of flux. The amount of ascertained decrease of latitude at the end of the six months' period from August 1889 to February 1890 was half a second. But it was notified to the Conference that the Berlin observations for the half-year ending last August showed an increase of latitude amounting to 0·4, or two-fifths of a second. In other words, the fluctuation of the axis is due to a minute oscillation, probably owing to some changes in the internal mass of our planet, and not to be confounded with the precession of the equinoxes.

WE are glad to note that in his address at the opening of the present term at the Johns Hopkins University, Dr. Gilman, the President, was able to speak of the prosperous material condition of the institution after its recent difficulties. Many friends came forward to support the University in its time of trial; and the trustees have been able to make a most advantageous change in a considerable part of the endowment, so that a million of dollars, lately unproductive, now stand invested in an excellent security yielding a fixed and satisfactory income. Dr. Gilman devoted a part of his address to an account of the impressions produced upon him during his recent travels in Europe.

THE new number of the *Internationales Archiv für Ethnographie* (Band iii., Heft 5) opens with a valuable and interesting paper (in German) on Venezuelan clay vessels and figures both of ancient and of modern times, by Dr. A. Ernst, Curator of the National Museum at Caracas. Among the remaining articles is one in English, by Prof. Giglioli, on a remarkable and very beautiful ceremonial stone adze from Kapsu, New Ireland. The illustrations are up to the usual high level maintained by this admirable periodical.

MESSRS. G. PHILIP AND SON have issued a second edition of "The Unknown Horn of Africa," by the late F. L. James. This edition is preceded by an obituary notice of the author, who was killed by a wounded elephant on April 21, 1890, at San Benito, about 100 miles north of the Gaboon River on the west coast of Africa, and within a mile and a half from the shore.

THE Sanitary Institute has published a volume of Transactions, which, as vol. x., continues the series issued by the Sanitary Institute of Great Britain. It contains a full report of the Congress held at Worcester in 1888. Among the contents are papers on the sanitary aspects of the pottery manufacture, by Dr. J. T. Arlidge; on the public health in India, with special reference to the European army, by Sir H. S. Cunningham; sewage disposal, by Prof. H. Robinson; the technical education of plumbers, by Mr. H. D. Matthias; some recent results obtained in the practical treatment of sewage, by Dr. Percy F. Frankland; and the smoke nuisance, under the Alkali Acts, by Mr. H. Fletcher. We may also note a lecture to the Congress, by Sir Douglas Galton; and addresses to the working classes, by Prof. W. H. Corfield, Mr. Henry Law, and Dr. J. F. J. Sykes.

AMONG the contents of the "Papers and Proceedings of the Royal Society of Tasmania for 1889," just received, is an excellent note by Colonel W. V. Legge, R.A., on the Australian curlew and its closely allied congeners. Dealing with the migrations of the Australian curlew, he says it migrates north through the Malay Archipelago, being there met with on passage in Borneo, New Guinea, the Philippines, and other islands; thence northward along the coast of China to Amoor Land, and up to Lake Baikal, in which region it is supposed to breed. In Japan, it has been met with as far north as Hakodadi. New Zealand seems to be its eastern limit.

DR. P. KUBORN, of the University of Liége, has prepared a French adaptation of Prof. D. J. Cunningham's "Manual of Practical Anatomy." The work is called "Guide de Dissection, et Résumé d'Anatomie Topographique." It is published by Marcel Nierstrasz, Liége; and G. Carré, Paris.

MR. WILLIAM HEINEMANN has published the "authorized translation" of Dr. Koch's paper on the cure of consumption—the paper contributed to the *Deutsche Medizinische Wochenschrift*.

A DISCOVERY, which may lead to important results, has been made by M. Chabrié during the course of his experiments upon the properties of the recently isolated gaseous fluorine substitution products of marsh gas. The intimate relation between these bodies and chloroform, and the possibility of their possessing even greater physiological activity, led M. Chabrié to investigate the action of one of them, methylene fluoride, CH_2F_2, upon specific microbes, with the result that in the case of the particular bacillus experimented upon, the gas is found to absolutely destroy them. The bacteria in question, which have formed the subject of these first experiments, were those discovered by M. Bouchard, in 1879, in urine. Two eprouvettes of equal size were taken and filled with mercury over a mercury trough. Equal small quantities of urine containing colonies of the bacteria were introduced into each, and afterwards a mixture of air and methylene fluoride admitted into one of the eprouvettes, and an equal volume of air alone into the other. The two vessels were both maintained at the temperature of the body, 35°, for 24 hours. At the end of this time a few drops of the urine from each of the vessels were introduced into separate flasks containing sterilized culture medium, and both maintained at the same stove temperature for 24 hours, and again for 48 hours. At the expiration of this period the urine which has stood in contact with air alone was found to have given rise to a flourishing colony of the bacteria, while that which had been in contact with the mixture of air and methylene fluoride had not given rise to a trace of a culture. According to MM Albarran and Hallé, twelve hours are ample for the development of this bacillus, hence methylene fluoride had evidently been fatal to the germs. The experiment was again repeated without the use of mercury, in sealed tubes, but with the same result. It appears, therefore, that methylene fluoride possesses the property of destroying the urinary bacteria in question. M. Chabrié has made special experiments in order to determine whether the gas possesses any local irritant action, and the results as far as they go appear to be eminently satisfactory. He is now directing his experiments upon the microbe of the hour, that of tuberculosis, and his results will doubtless be watched with considerable interest. Methylene fluoride is easily prepared by heating silver fluoride with methylene chloride in a sealed tube. M. Chabrié has also succeeded in preparing the higher homologue, $C_2H_4F_2$, ethylene fluoride, by the analogous reaction with ethylene chloride, and is extending his observations to the antiseptic properties of this latter gas. An account of the above experiments is given in the current number of the *Comptes rendus*.

OUR ASTRONOMICAL COLUMN.

A NEW COMET (?).—The following is an account that was received through Reuter, and printed in the *Times* on Monday last, relating to a comet that was visible at Grahamstown. If the statement is correct, we have represented here something that is quite unique in cometary phenomena. It has still to be explained how it was that a phenomenon of such a nature as this was not telegraphed home at the time, and why no confirmation has been received from other sources.

"*Cape Town, November* 5 (*viâ Plymouth*).

"Mr. Eddie, F.R.A.S., reports from Grahamstown that a comet was seen at 7.45 p.m. on the 27th ult., and observed until 8.32 p.m., when the last trace faded in the south-eastern heavens. It travelled from nearly due west around the western and southern horizon at an altitude from about 20° to 25°, and disappeared in the south-east, performing during that very brief interval a journey stretching over at least 100°. It was at its longest fully 90° in length, while in width it did not exceed half a degree, except where it became very faint and slightly spread out at its posterior extremity, and where there were also faint indications of lateral division. The preceding portion was a point in cometary form, but no nucleus could be discerned.

"When first seen, it was inclined at an angle of about 45° towards the south, and was about 30° in length, but as it moved southward it became almost parallel to the horizon, with an altitude of about 20°, till it stretched along the southern horizon an enormously long, narrow, almost parallel, weird-looking riband of gray light moving visibly across the sky. It passed over several bright stars, notably α Centauri and β Argo Navis, but did not appear to dim their lustre. The moon was at the full."

THE STARS 121 AND 483 BIRM.—Mr. Backhouse informs us that these irregular variable stars now appear to be near their maxima. He says:—"They are two of the most splendid red stars that are visible in a moderate-sized telescope; 483 is the deepest-coloured star that I am acquainted with of anything like its brightness, with the exception of R Leporis; 121 is usually nearly as deep, but at present seems not so red as usual." Dunér has described the spectrum of each as Group VI. (Class III.*b*), but, as pointed out by Mr. Backhouse, it is possible that there may be variations with the maximum of luminosity, especially as one of them appears to have changed colour. The positions of the stars are 5h. 39m. 6s., + 20° 39′, and 18h. 58m. 32s., − 5° 51′ respectively.

APEX OF THE SUN'S WAY.—In *Astronomische Nachrichten*, Nos. 2999, 3000, Oscar Stampe gives an extended investigation into the position of the apex of the sun's way. The following are the numbers and groups of stars considered, and the values obtained:—

	Number of Stars.	Yearly Proper Motion.	Co-ordinates of Apex. R.A.	Decl.
Group 1	551	0″·16 to 0″·32	287°·4	+42°·0
,, 2	340	0·32 to 0·64	279·7	+40·5
,, 3	105	0·64 to 1·28	287·9	+32·1
,, 4	58	1·28 and over	285·2	+30·4
		Mean	285°·0	+36°·2

This agrees well with the values found by Boss (*Astronomical Journal*, 213), viz.:—R.A. 280°, Decl. +40°, and does not differ considerably from Struve's values, viz.:—R.A. 273°·3, and Decl. +27°·3, or +37°·7, if Boss's correction be applied. The position of the apex may therefore be taken as somewhere near Vega.

ORBITS OF 61 CYGNI, CASTOR, AND 70 OPHIUCHI.—In the November number of the *Sidereal Messenger*, Mr. N. M. Mann discusses the orbits of these three interesting binaries. The period of 61 Cygni is shown to be 462 years. If this be so, then, taking the parallax of the binary as 0″·55, the mass of the system is 1·45 times that of the sun. In a previous note (*Sidereal Messenger*, vol. ii. p. 22) the author found a period of 1159 years, whilst the combined mass of the connected bodies was concluded to be only one-seventh the sun's mass. New orbits have been calculated for Castor and 70 Ophiuchi. The latter star has made an entire revolution since the first good observation, hence it is probable that the elements computed are correct, and that the places given may be relied upon for many years.

TWO NEW COMETS (*e* AND *f* 1890).—Dr. Copeland announces, in *Edinburgh Circulars* Nos. 10 and 11, the discovery of a rather bright comet, by Prof. Zona, at Palermo, on November 15, at 10h. 24·1m. local time. Its position then was R.A. 5h. 35m. 54·8s., Decl. N. 33° 23′; daily motion *minus* 5m. 32s., and *plus* 17′. This comet was observed at Kiel on the following day at 9h. 1·1m. in R.A. 5h. 30m. 46·3s., and Decl. N. 33° 37′ 6″.

Dr. Spitaler discovered a faint comet, not identical with the above, at Vienna, on the 16th inst., its place at 16h. 32m. local time then being R.A. 5h. 27m. 16·93s., Decl. N. 33° 37′ 16″. It was in the constellation Auriga, and moving slowly towards the north-east, like Zona's comet.

THE STAR D.M. + 53° 2684.—The Rev. T. E. Espin announces (*Wolsingham Circular* No. 28) that this star, 710*a* in the Espin-Birmingham Catalogue, R.A. 21h. 37m. 6s., Decl. + 53° 49′ (1890), was observed in the spring as 7·5–8·0 magnitude, but on November 15 was only of the ninth magnitude. The star is very red, with a magnificent spectrum of the third type (Group II.).

MATABELELAND.

AT the meeting of the Royal Geographical Society on Monday evening, Lieutenant E. A. Maund read a paper on Matabele and Mashona Lands. Mr. Maund was with Sir Charles Warren in South Africa in 1885, when he traversed and reported on Matabeleland. Since then he has spent much time in the country, accompanying Lobengula's two envoys to England about two years ago. He has thus had exceptional opportunities of observing both country and people, and moreover has had access to the official reports of Colonel Pennefather, the leader of the Pioneer Expedition into Mashonaland. After some introductory remarks, Mr. Maund proceeded to give a description of the country:—

"The physical features noticeable in Bechuanaland extend to the high veldt plateau of the Matopo Range, formed by vast sand-belts running east and west, varying in breadth from a few thousand yards to 50 miles, and in elevation, the crest above the trough, from a few feet to several hundred. These belts carry good grass and bush with camel-thorn trees, the bush being invariably thickest on the crest, but necessarily lacking a surface water-supply. This marked feature extends, with a few accidental variations caused by the outcropping of granite, limestone, and basaltic hills, probably from Namaqualand and Damaraland on the west to the Basuto Transvaal and Mashona Mountains on the east, and beyond the Zambezi northwards.

"The cause of these mysterious sand-belts suggests a problem in physical geography which must be left to geology to decide. They must have been raised in their present wave-like formation either by the aid of water or by a constant and powerful wind. The theory that this part of Africa was an elevated basin, which has gradually drained Zambeziward, is the most acceptable, as in the greatest depression about Lake Ngami and along the fertile valley of the Chobe there is still abundance of water. The continual washing backward and forward of the water has disintegrated the old red sandstone upper crust, and left the red sand in this formation like, on a small scale, the sand-ridges left on our sea-shore by the receding tide; while the kopjes of granite, which all have one form, stand out like rocks at low water.

"These kopjes are rocky hills, with the summits apparently denuded, leaving a flat table-top with short cliff-like edge, the *débris* having fallen in slopes at an angle of 45°, as though crumbled off as the tide fell. Beneath the sand formation is generally to be found a limestone sedimentary crust, which in the Kalahari undoubtedly preserves the water underneath from evaporation. Thus at a fountain near Vryburg, between Motito and Takoon, 20 feet beneath the surface there is a running stream 57 feet deep, doing no good to the soil, simply because it wants man, aided by science, to prevent its thus running to waste. The sandstone conglomerates at Kanje and Molopolali, and the banket formation in Matabeleland, were possibly formed by infiltration during this water age. The results of its energetic action is seen in the Matopo range, where you find hills formed of a single block of granite, looking in the distance like our Downs, but on closer inspection this gentle slope is rounded off and polished by the action of the sand-laden water. Detrition has made it as smooth as the shingle-pebbles on our shores. These hills are a favourite haunt of baboons, as immediately they are disturbed they scamper over the steepest and roundest hills, where you cannot follow them. There is apparently no glacial action, but *moulins* I have frequently found of all sizes in the smooth surface, often with the rounded boulder *in situ*. Indeed, for a long time, until I found them large and the boulder there, I had taken them for old Mashona mills, either for crushing corn or quartz, and subsequently I found these people do utilize the smaller for the former purpose. Geologists now by a closer examination will doubtless come across fossils in the limestone crust and sand, which will decide the question as to there having been a large lake since dried up, or one gradually run off, owing to a breach having been made through the outer rim by some convulsion where the Zambezi now flows out. This lake theory was a favourite speculation of Livingstone.

"With regard to the vegetation being thickest on the crest of the belts, I can only suggest that whatever moisture falls quickly finds its way to the valleys; consequently the grass grows more luxuriantly there. The grass in these valleys, after good rains, is often 4 to 6 feet high, and, as the natives yearly burn the grass when it is driest, it naturally follows that the fire is fiercest in the bottoms than over the crest, where grass is sparse from lack of moisture. Bush and trees perish in the dells, but live through the ordeal above, and often ultimately become so thick as to be impenetrable. It is on the high veldt among the Mashona hills that the rich reefs lie, once so well worth working in prehistoric times, as is evidenced by the old workings to be found all over the country; while the rich watered valleys, from whose streams the natives now wash their quills-full of gold, are capable of raising crops and feeding cattle for the support of a large European population.

"Before going into details I would draw your attention to the map of Matabeleland and Mashonaland. It practically lies between the parallels of 16° and 22° S. lat. and the meridian of 27° to 23° E. long., and is certainly the most promising country for colonization in South Africa. Compared with the country south of it, Matabeleland is like Canaan after the wilderness; lying high, generally healthy, and very rich in minerals—gold, copper, and iron having been extensively worked by the ancients with their rude appliances. Its numerous rivers are either running, or have plenty of water in them. The soil is rich and admirably adapted for corn; cattle thrive, and there is an abundance of grass and wood. White children can be reared in the country, which is a *sine quâ non* if it is to be successfully colonized by white men; and, above all, it is sparsely populated.

"The country dominated by the Matabele is nearly as large as Germany, while the territory actually occupied by them is very small, and would compare about as Bavaria does to the German Empire. Their kraals occupy the plateau forming the watershed between the Zambezi and the Crocodile Rivers. They are a Zulu military organization, occupying a rich country which they have depopulated, and live under a despotism of the worst kind. The population may be estimated at about 150,000, and it has become a mixed people of Zulus, Bechuanas, Mashonas, and Makalakas from the incorporation of conquered elements. Their fighting strength is probably not over 14,000 to 15,000 men."

After referring to the history of the Matabele, and to King Lobengula, and giving some account of the visit of the envoys to England, Mr. Maund went on to speak of the country which has just been opened up by the Pioneer Force.

"The country about to be opened up for colonization is," he stated, "an extensive plateau, on the water-parting between the Zambezi and the Crocodile Rivers. There are no mountain peaks. To the east the slope of the land is abrupt and the country broken, many of the hills isolated and very conspicuous, while to the north-west it falls in gentle undulations. The plateau is furrowed by many considerable rivers, and their numerous tributaries. The climate in these highlands, which vary from 3000 to 5000 feet above sea-level, is far more healthy than the now well-colonized sea-board of South Africa. The seasons are well marked, and the rainfall good. For eight months, from April to November, the air is particularly dry and salubrious, and compares well with the Free State. During and just after the rains one must be careful, as in all tropical climates. But, with proper precautions, dwellings placed high, and above exhalations from the marshes left by the subsiding rivers, and above all a judicious abstinence from alcoholic drinks, the new mining and farming communities will be as healthy as are the missionaries who have lived so long there with their families.

"Here let me pay a tribute to these silent workers, whose genial hospitality and kindly attention in case of sickness is bestowed on travellers throughout Africa. In Matabeleland as elsewhere they have been the pioneers of civilization. A heart-breaking up-hill work has theirs been for the past five-and-twenty years among the truculent Matabele, and though their converts are few, their example is beneficial to whites and blacks alike. They have built comfortable brick houses, laid on water from brooks and springs, and irrigated gardens which show the capabilities of the soil. The King, it is true, is the only one at present who dares copy them: he has a large commodious brick house put up by their builder; he has too an irrigated garden after their pattern. Now, let us hope, their harvest will come, for with the advent of a white population the old order of things will quickly change in Matabeleland. The example of their health will also be an incentive to our countrymen to house themselves as quickly as possible, or we shall have direful stories of fever, simply resulting from a lack of those comforts to which they have been used, and which up here will be a necessity.

"During the last rainy season, in the months of November, December, January, and February, the rainfall in the neighbourhood of Baluwayo amounted to upwards of forty inches. Like all tropical rains they are not continuous, but come in terrifically heavy thunderstorms with hot sunshine between. At this time the King is very busy with his witch doctors, rain-making; often painted with medicine charms in bands like a tiger, or making a dreadful concoction, called by the traders 'hell broth,' to please his credulous people, who come to beg rain for their gardens.

"The months of September and October, before the rains, are the hottest in the year. All vegetation appears dried up, and the grass lands are burned off by the natives. Cattle grow thin, and are sent off low down the rivers to find grass and water. The natives have, of course, no knowledge of how to store their generous rainfall. In September I have registered a maximum in the shade ranging between 105° and 111° F., but the atmosphere is so dry that it is more easily supported than 85° near the sea-coast, where the air is saturated with moisture. The evenings and mornings are delightful, and on this high ground the heat is never enervating. During the winter months, May, June, and July, it is very cold at night in these highlands. Even on the Macloutsie River, at an elevation of 2500 feet, I have registered 15° of frost at night, with the thermometer ranging up to 80° in the day (observed with instruments registered at Kew). Mealies—that is, Indian corn—put in soak for the horses over night, have been frozen hard in the morning.

"Notwithstanding this great variation in temperature, the dry season is particularly healthy. What, however, braces the white man withers up the unclothed native. Trek oxen suffer too from this cold, and the dryness of the grass. By these remarks I wish to convey the fact that with ordinary care this country is admirably adapted to colonization by us Anglo-Saxons. Englishmen have lived up there for the last twenty years, and, what is more essential, traders and missionaries have reared large families. There is not the necessity for sending them home as with Indian children. Neither need men, as on the west coast, return home periodically, in order to recruit. Here they may make a permanent home."

After speaking of the immense agricultural capabilities of the country and of its mineral riches, Mr. Maund gave some account of the particular district through which the Pioneer Force passed:—

"Passing out of Khama's country, the B. S. A. Company's expedition found a fair agricultural country, rising only 500 feet in the 150 miles between the Tuli and Lundi. The former river is 400 yards wide at the drift. Half a dozen new rivers, whose euphonious names I need not trouble you with, are reported as running south-east to the Crocodile. At first the road led through a bush and mopani veldt, while the latter 90 miles consists of grazing flats interspersed with granite and sandstone kopjes. It is sparsely populated by Makalakas and Banyai, who are tributary to Lobengula.

"After the Lundi, the elevation gets sharper and the country more difficult; there is a rise of 1500 feet in less than 65 miles to the top of the Providential Pass, the only apparent pass (and that 8 miles long) leading from the low to the high veldt. At the Inkwe (? Tokwe) the height above sea-level is 2700 feet. This is a rapid river with water 50 yards wide and 3 feet deep, even in the dry season. The formation here changes from granite to slate, and the gold indications are very good. We are now among the ancient workings of Benmatapa, Monomotapa, or Quiteve. Twelve miles east in the mountains are the grand ruins of its ancient capital, Zimbabye, or Zimboe.

The many and vast remains of ancient buildings all point, from their propinquity to old workings, to an extensive gold industry, when the means of extraction were crude as compared with modern appliances. The country gradually rises into an undulating plateau ranging from 4530 to 5000 feet above sea-level, with park-like scenery, the eastern edge breaking away into rocky gorges, supplying many tributaries to the Sabi. The water-shed between this river and the Zambezi's tributaries is often very narrow; 100 yards would sometimes only separate the streams running to the two basins. There are apparently no inhabitants on this plateau south of the Hanyani, so cruelly have Matabele assegais done their work.

"The bush is thick and the land boggy at the head waters of these rivers, but beyond the Umfuli there are plains from which Mount Hampden rises, stretching away to the head waters of the Mazoe. The neighbourhood of Fort Salisbury is well wooded, and the petty tribal chiefs welcomed the English force, as promising them security. Prospectors are reporting favourably from all directions, and find old workings wherever they go."

Mr. Maund concluded by referring to the famous Zimbabye ruins, which he seems inclined to think are Phœnician, or at least early Arabian. But Mr. Theodore Bent, who spoke after the reading of the paper, was strongly of opinion that they are of Persian origin.

THE CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES OF THE BRITISH ASSOCIATION.[1]

At the first Conference, held on September 4, the chair was taken by Mr. G. J. Symons, F.R.S. The Report of the Corresponding Societies Committee was taken as read. Subjects of interest to the Corresponding Societies were then discussed in the order of the Sections of the Association.

Section A.

Temperature Variation in Lakes, Rivers, and Estuaries.—The Chairman stated that many thermometers had been distributed, and much information had been collected during the year.

Mr. W. Watts stated that he had been conducting temperature observations in two large reservoirs belonging to the Oldham Corporation, the results of which were included in the Report of the Committee.

Mr. Cushing presented a report of weekly temperature observations taken in the River Wandle, in Surrey. The temperatures were taken between 3 and 3.30 p.m. on Sunday afternoons, and extended from October 1888 to February 1889. The observations were taken at ten different stations. The records were accompanied by a statement of the mean weekly shade-temperature, and the rainfall for the previous week. The observer, Mr. F. C. Bayard, was willing to continue the work.

The Chairman stated that he had recently been reducing experiments on evaporation which had been made for several years at Strathfield Turgiss, in Hampshire, in which the ordinary small evaporators had been compared with a tank 6 feet square and 2 feet deep. Evaporation from the tank averaged 15 inches per annum, while the smaller evaporators (owing to the high temperature of the water) indicated considerably in excess of the truth.

Meteorological Photography.—Mr. Hopkinson alluded to the success which had been achieved by the Committee on Geological Photography, and pointed out the growing importance of photography in other branches of scientific research. He then suggested the appointment of a Committee on Meteorological Photography. Photography, he said, could most advantageously be applied to the investigation of meteorological phenomena, such as the forms of clouds, lightning-flashes, and the effects of storms. The Committee would collect the photographs and keep a register of them. The study of the forms of clouds would be more satisfactory if undertaken by a comparison of photographs than of drawings; methods of overcoming the difficulty of photographing light clouds in a blue sky might be investigated; and the various phenomena connected with lightning-flashes would be a most interesting field for research. Photographs showing the effects of storms should be secured as soon as possible. If a Committee were formed, Mr. Symons and Prof. Meldola would consent to serve on it, and Mr. A. W. Clayden would be willing to act as Secretary.

After some discussion, it was decided that application should be made through the Committee of Section A for the formation of a Committee on Meteorological Photography, and that the application should be supported by a recommendation from the Conference of Delegates.

Section C.

Sea-coast Erosion.—Mr. Topley asked assistance for the Committee investigating this matter.

Erratic Blocks.—The Rev. E. P. Knubley stated that the Yorkshire Naturalists' Union had been recording erratic blocks satisfactorily; twenty-five reports had been presented.

Geological Photography.—Mr. O. W. Jeffs stated that, through the action of the Conference of Delegates at the previous meeting of the Association, a Committee had been appointed for collecting and reporting on geological photographs. Much assistance had been rendered to this Committee by delegates from the Corresponding Societies, many of whom had sent photographs, or lists of those that had been taken. The photographs had been arranged in order to select those which illustrated well-defined strata or sections. The Report showed that many of the counties of England and Wales were as yet unrepresented, and he asked those delegates who had not yet done so to bring the matter before their Societies, and to interest photographers in the work. The object of the Committee was to secure a series of photographs illustrating the features which geologists thought best worth recording in their respective localities. The counties from which photographs had been received were: Dorsetshire, Cornwall, Devonshire, Isle of Man, Kent, Lancashire, Montgomeryshire, Nottinghamshire, Suffolk, Shropshire, and Yorkshire; there were also a few from North Wales, Scotland, and Ireland. The Yorkshire Naturalists' Union had contributed over 100. A large number of the photographs were exhibited in the room of Section C.

Prof. Bonney testified to the zeal and energy of Mr. Jeffs as Secretary to the Committee, and suggested that, when a large collection of photographs had accumulated, some of the more typical examples of geological phenomena might be enlarged for publication.

Mr. Jeffs suggested that the Committee might make arrangements with some photographer for preparing lantern-slides from the photographs for the purpose of illustrating lectures.

Mr. Wm. Gray thought that it would be an advantage if each delegate were appointed the local representative of the Committee in his own district, and authorized to collect the photographs; he would be willing to act in this capacity for the north of Ireland.

Prof. Meldola pointed out that, in taking photographs of geological sections, in which differences in the strata were often indicated only by small differences in colour, it would be an advantage to use orthochromatic plates.

The desirability was then discussed of adopting some means by which members of the British Association, and those who assisted in the work, might be enabled to procure copies of the photographs, either as lantern-slides, prints, or enlargements, and various suggestions to this end were made.

Section D.

Disappearance of Native Plants.—Prof. Hillhouse stated that the third Report of the Committee on this subject had been confined to the north of England, the Isle of Man, and to a few records from South Wales. The bulk of the material had been obtained directly by correspondence with the local Natural History Societies, especially the Yorkshire Naturalists' Union. Next year's Report would probably deal with the whole of Wales, and possibly adjoining counties and the south-west of England. He then gave a *résumé* of the Report, stating that it contained an account of the more or less complete disappearance from certain localities of about seventy species. In some cases the disappearance was due to natural causes, but in most to the action of man.

Mr. Hopkinson stated that nearly the whole of the ferns in his district (St. Albans) had disappeared within the last twenty years. He attributed this to London collectors and dealers, and added that there was danger of even the primrose being exterminated from the neighbourhood of London, as the roots were taken there by cartloads every year.

Mr. M. B. Slater suggested that the best plan to obtain rare plants for cultivation would be to procure a little ripe seed and

[1] Abridged from the official Report which has recently been issued to the Corresponding Societies.

to try to raise it. He had by this means under cultivation some of our rarest British plants.

Investigation of the Invertebrate Fauna and Cryptogamic Flora of the Fresh Waters in the British Isles.—The Rev. E. P. Knubley stated that a Report of the Committee for this purpose had been presented, and that the Yorkshire Naturalists' Union had been steadily working at the subject during the past year.

SECTION G.

Flameless Explosives.—Prof. Lebour stated that the North of England Institute of Mining Engineers had continued experimenting on this subject; the South Wales Society had already helped; and one or two smaller societies had promised assistance. The result of the joint work of the Committee which had been appointed would soon be published.

SECTION H.

Catalogue of Prehistoric Remains.—Mr. Kenward said that the Birmingham Philosophical Society was recording the few ancient remains in its district. He had worked himself, and had induced others to promote the suggestions made at the Conferences at Bath and Newcastle, as well as to assist in carrying out the archæological survey proposed by the Society of Antiquaries.

Mr. Gray stated that the Belfast Naturalists' Field Club had taken the matter up, and would continue to co-operate with the Committee of the Association.

The Chairman remarked upon the advantage of being able to have at hand for reference the publications of the local societies collected by the Corresponding Societies' Committee for the purpose of preparing the catalogue of papers which formed part of their annual Report, and also called attention to the fact that a few of the older and well-known local societies had not yet become enrolled as Corresponding Societies.

The Second Conference took place on September 9, Mr. G. J. Symons, F.R.S., in the chair.

SECTION A.

Temperature Variation in Lakes, Rivers, and Estuaries.—Prof. Meldola read a communication from Dr. H. R. Mill, the Secretary of the Committee, on this subject, thanking the local societies for their assistance, and stating that the work of observers who are members of such societies is, as a rule, more regular and more accurate than that of isolated volunteers. It was desirable, he said, that the societies already assisting should continue to make observations for another year with as much regularity as possible. Additional observers were not required, as sufficient data for the purposes of the Committee were in course of being secured.

Meteorological Photography.—Mr. Hopkinson reported that the formation of the proposed Committee on this subject had been sanctioned by the Committee of Section A, and that the form of application had been forwarded to the Committee of Recommendations.[1]

SECTION C.

Prof. Lebour, representing the Committee of this Section, brought under the notice of the delegates the following Committees recommended for appointment or reappointment:—

(1) *Erratic Blocks.*—The co-operation of the Corresponding Societies which had not yet taken part in the observations was invited.

(2) *The "Geological Record,"* the continuation of which had been recommended, with a grant.

(3) *Underground Waters,* of the work of which Committee the Secretary, Mr. De Rance, would speak.

(4) *Exploration of Oldbury Hill.*—A Committee had been recommended for excavating this ancient earthwork, which was near Ightham, in Kent.

(5) *Geological Photography.*—This Committee, of which Mr. Jeffs was Secretary, had been recommended for reappointment.

(6) *Northamptonshire Lias.*—A Committee for collecting and registering the fossils of this formation had been recommended for appointment, and excavations had already been commenced.

[1] The Committee, consisting of Mr. Symons (Chairman), Prof. Meldola, Mr. Hopkinson, and Mr. Clayden (Secretary), was duly appointed, with a grant of £5.

(7) *Sea-coast Erosion.*—This Committee had been recommended for reappointment.

(8) *Registration of Type-Specimens.*—A recommendation had been sent in for the appointment of a Committee for reporting on type-specimens in museums, an important subject, in which great assistance might be rendered by local societies.

(9) *Earth Tremors.*—This Committee had been recommended for reappointment, with Mr. Davison as Secretary.

(10) *Exploration of Elbolton Cave.*—A Committee had been recommended for the exploration of this cave, which was near Skipton, and in which relics of human occupation had already been found.

(11) *Source of the River Aire.*—The object of the Committee, recommended for appointment for the purpose of investigating this question, was to ascertain, if possible, by means of the coal-tar colouring-matter, fluoresceïn, whether the water which flows out of Malham Tarn and disappears down a "water-sink" to the south of the tarn, is the stream which emerges at Malham Cove or Aire Head, or at both these places. The use of the dye for this purpose had been suggested by Prof. Meldola to Prof. S. P. Thompson, and the latter had brought the subject before Section C. It had been suggested that the method might be found generally useful for investigating the course of underground waters, as a very small trace of the dye produced an intense green fluorescence.

Mr. De Rance, who also represented Section C, remarked on the work of the Underground Waters Committee, that its objects were to study underground water with a view to supply from wells and springs. Questions were asked respecting the quality, quantity, and level of the water. The Committee wished for records of water-level extending over long periods of time, and especially to secure old records. The work of the Coast-erosion Committee had been carried on with important results, and much information had been derived from a study of old charts. The Committee on Erratic Blocks, of which Dr. Crosskey was the Secretary, was appointed in 1871 with the object of recording the exact positions of the more important boulders, and of entering these positions on the Ordnance maps. It was important to have a microscopical examination made of sections of chips from the boulders, so that their probable sources might be ascertained. Another point was that the boulders should not be left to the mercy of the stone-breaker, but should be preserved.

Prof. Meldola stated that he had been requested by Dr. Crosskey to thank the Corresponding Societies for the aid they had already given, and to express the hope that their assistance would be continued.

SECTION D.

Phenological Observations.—Mr. Symons introduced this subject, which, he said, might perhaps be considered to have originated with Gilbert White, but received little attention in England until 1874, when the Meteorological Society obtained the assistance of delegates from several Natural History Societies, who held a number of meetings and drew up a Report. Plants, insects, and birds were referred respectively to the Rev. T. A. Preston, Mr. McLachlan, and Prof. Newton. Of plants, 71 species were recommended for observation, of insects 8, and of birds 17. From 1875 to 1878 the Rev. T. A. Preston prepared, and the Royal Meteorological Society printed, annual Reports embodying the results obtained. Mr. Preston finding it impossible to continue the work, Mr. E. Morley took it up and prepared the Report for 1889. On his suggestion the list had now been reduced to 13 plants, 3 insects, and 5 birds, and the Council of the Royal Meteorological Society desired to enlist as many observers as possible, and to obtain the assistance of the Corresponding Societies of the British Association.

A discussion ensued as to the suitability for observation of the species selected. In concluding it, Mr. Symons said that he had brought the matter forward more as a meteorologist than as a naturalist, and he thanked the delegates for their suggestions.

SECTION E.

Teaching of Geography in Elementary Schools.—Mr. Sowerbutts said that he had undertaken to draw up for Section E a Report on this subject with reference to the action of local authorities, in order to make known how far the Government grant for technical education or allied purposes was made use of for the teaching of geography, and he asked the delegates to assist him by sending in School Board Reports, &c.

SECTION H.

Committee of Aid for Anthropological Excavations.—Dr. Garson called attention to the existence of a Committee of Aid formed by the Anthropological Institute for the purpose of aiding by direction or otherwise the exploration of ancient remains, the Chairman of this Committee being General Pitt-Rivers, the Inspector of Ancient Monuments. Local societies, he said, would find it to their advantage if they would report to this Committee when they were desirous of undertaking explorations.

Prehistoric Remains Committee.—Mr. J. W. Davis said that this Committee, of which he was Secretary, wanted a record of everything that had reference to prehistoric man, his dwellings, implements, pottery, &c.

A discussion then took place with reference to the best method of imparting to the Corresponding Societies through their delegates a knowledge of what had taken place at the Conferences. Mr. Hopkinson suggested that each delegate should read a paper before his Society, giving an account of the work taken up by the various Committees, and that this paper should be published by that Society, so as to be accessible to every member of it. He distributed amongst the delegates a paper on the work of the Committees of the Association which he had brought before the Hertfordshire Natural History Society. Another question raised was the advisability of in some way bringing into relationship with the British Association certain societies which did not come up to the standard of excellence requisite for enrolment as Corresponding Societies.

On the motion of Prof. Lebour, seconded by Mr. J. W. Davis, a vote of thanks was passed to Mr. Symons, Chairman of the Conference, and to Prof. Meldola, Secretary.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Love, Fellow of St. John's College, has been elected Chairman of the Examiners for the Mathematical Tripos, Part I.

Prof. Darwin, Prof. J. J. Thomson, Mr. Pendlebury, St. John's, and Mr. Lachlan, Trinity, have been appointed Examiners for the second part of the Mathematical Tripos.

Mr. E. A. Parkyn, Christ's, and Mr. M. C. Potter, Peterhouse, have been appointed Lecturers in Science at affiliated lectu re-centres.

Scholarships and Exhibitions in Natural Science will be open for competition to non-members of the University in December and January next at the following Colleges: King's, Jesus, Christ's, St. John's, Trinity, Emmanuel, and Sidney Sussex (see *Cambridge University Reporter*, November 18, 1890, p. 237).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Meteorological Society, November 19.—Mr. Baldwin Latham, President, delivered an address on "The Relation of Ground Water to Disease." The pages of history show that when the ground waters of our own or other countries have arrived at a considerable degree of lowness, as evidenced by the failure of springs and the drying up of rivers, such periods have always been accompanied or followed by epidemic disease. In all probability ground water in itself, except under conditions where it is liable to pollution, has no material effect in producing or spreading disease. As a rule, it is only in those places in which there has been a considerable amount of impurity stored in the soil that diseases become manifest, and the most common modes by which diseases are, in all probability, disseminated, are by means of the water supplies drawn from the ground, or by the elimination of ground-air into the habitations of the people. It is found that the periods of low and high water mark those epochs when certain organic changes are taking place in the impurities stored in the ground, which ultimately become the cause and lead to the spread of disease. Mr. Latham defines "ground water" as all water found in the surface soil of the earth's crust, except such as may be in combination with the materials forming the crust of the earth. It is usually derived from rainfall, by percolation; and it is also produced by condensation. In dry countries, ground water is principally supplied by the infiltration from rivers, as, for example, in the Delta of the Nile. The absence of water passing into the ground for a long period naturally leads to the lowering of the free ground water-line, and may lead to the drying of the ground above the water-line; and it is curious to note, with reference to small-pox, that the periods marking the epochs of this disease are those in which there has been a long absence of percolation, and a consequent drying of the ground preceding such epidemics. On the other hand, small-pox is unknown at such periods as when the ground has never been allowed to dry, or is receiving moisture by condensation or capillarity. The study of underground water shows that certain diseases are more rife when waters are high in the ground, and others when the water is low. The conditions that bring about and accompany low water, however, have by far the most potential influence on health, as all low water years are, without exception, unhealthy. As a rule, the years of high water are usually healthy, except, as often happens, when high water follows immediately upon marked low water, when on the rise of the water an unhealthy period invariably follows. Mr. Latham has found that those districts which draw their water supplies direct from the ground, are usually more subject to epidemics and disease than those districts in which the water supply is drawn from rivers supplied from more extended areas, or from sources not liable to underground pollution. In the case of Croydon, one portion of the district (under three-fourths) is supplied with water taken direct from the ground, whilst the remaining portion is supplied with water from the River Thames. It is curious to note that even so recently as 1885 the zymotic death-rate in the districts supplied with underground water was twice as great as in that part of the district supplied from the Thames; and in this particular year forty-one deaths from small-pox occurred in the district, not one of which was recorded outside the district supplied by the underground water. Mr. Latham, in his address, dealt largely with zymotic diseases as affected by ground water, and showed that cholera ordinarily breaks out when there is the least ground water; a high air and ground temperature is also necessary for its development, and as a rule the low-lying districts are favourable to the production of these high temperatures. Small-pox is almost always preceded by a long period of dryness of the ground, as measured by the absence of percolation. Typhoid fever is most prevalent after a dry period, and the first wetting of the ground or percolation from any cause takes place. The condition essential to the development of diphtheria is a damp state of the ground marked by extreme sensitiveness to percolation of rain. Scarlet fever follows the state of the dryness of the ground, which is essential for its development, and it occurs in the percolation period. The conditions that precede small-pox are those favourable for the development of scarlet fever, and, like small-pox, the dampness of the ground for any considerable period in any particular locality, may check its development or render it less virulent, and it is most rife in low water years. Measles are least prevalent at the low water periods, and mostly rife at and near high water periods. Whooping-cough follows the percolation period in its incidence, increasing with percolation, and diminishing as the waters in the ground subside. Diarrhœa is generally more prevalent in a low water year than in other years; that is, with a very much colder temperature in a low water year there is a very much higher death-rate from this disease. Mr. Latham finds that the general death-rate of a district is amenable to the state of the ground water, years of drought and low water being always the most unhealthy.

Geological Society, November 12.—Dr. A. Geikie, F.R.S., President in the chair.—The President referred to the sad loss the Society had sustained since the last meeting, through the death of the late Foreign Secretary, Sir Warington W. Smyth, F.R.S.—The President reported that Mr. L. Belinfante had been temporarily appointed by the Council to the office of Assistant-Secretary.—The following communications were read:—On the porphyritic rocks of the Island of Jersey, by Prof. A. De Lapparent, Foreign Correspondent of the Society. (Communicated by the President.) The author had some years ago described as Permian a series of porphyritic rocks, of which specimens had been sent to him from Jersey. He had since been led to believe that this view of their age, arrived at from what he knew of similar rocks in France, was erroneous, and in a recent visit to the island had satisfied himself that the English observers who had assigned to these rocks a much higher antiquity were in the right. He now found that the igneous rocks in question underlie the Rozel conglomerate, which must be placed at the very base of the Silurian formations. He reserved his detailed statement for a communication to the Geological Society of France; his present object being to do justice to English geologists, whose views he had formerly opposed.—On a new species of *Trionyx* from the Miocene of Malta, and a Chelonian scapula from the London Clay, by R. Lydekker.—Notes on specimens collected by W. Gowland, in the Korea, by Thomas H. Holland, of the Geological Survey of India, late Berkeley Fellow of the Owens College. (Communicated by Prof. J. W. Judd). The southern half of Korea traversed by Mr. Gowland is of a hilly character. The rocks forming the hills are chiefly crystalline schists—gneisses with graphite, garnet, dichroite, and fluor occurring in considerable abundance; and the whole group is probably part of the great Archæan mass of North-East China. The author describes these metamorphic rocks in detail. Stratified rocks, probably of Carboniferous age, lie unconformably upon the schists in the south-eastern part of the peninsula, and petrographical notes of these are given in the paper. Through the crystalline schists and stratified rocks various igneous rocks have been erupted as dykes or in large masses. Amongst these the most conspicuous rock is granite. Biotite- and muscovite-granite are most widely distributed, and in places are cut by dykes of eurite and veins of quartz and pegmatite. The more basic class of rocks is represented by diorites, propylites, andesites, basalts, dolerites, and gabbros. Interesting cases of the gradual passage between the so-called intermediate and basic rocks are found, and various stages in the devitrification and decomposition of andesitic lavas represented. These are described in detail by the author, and compared with similar cases in other regions; and full descriptions of the intrusive rocks are furnished. There are now no active volcanoes; and there is a notable lack of mineral wealth in the southern part of the Korea. Prof. Judd spoke of the value of Mr. Gowland's geographical and geological discoveries, and the enthusiasm with which Mr. Holland had applied himself to the work of examining the specimens brought home, and he considered that the work would prove an important contribution to science. Several points about which difficulties had arisen by examination of European rocks had light thrown upon them by the Korean specimens. The President felt that the Society would agree with him in considering the Geological Survey of India fortunate in securing a petrologist like Mr. Holland.—Further notes on the stratigraphy of the Bagshot Beds of the London Basin (north side), by the Rev. A. Irving.

Mathematical Society, November 13.—J. J. Walker, F.R.S., in the chair.—The Chairman informed the members of the loss the Society had recently sustained by the death of Dr. A. J. Ellis, F.R.S., who was elected a member on June 19, 1865, and had served on the Council during the sessions 1866–67, 1867–68. He gave a brief sketch of Dr. Ellis's contributions to mathematics and other subjects. He next sketched in some detail the numerous contributions made to mathematical physics by Lord Rayleigh, F.R.S., dwelling more particularly upon those memoirs which had led the Society, as announced at the June meeting, to award him the De Morgan Memorial Medal. The medal having been presented, Lord Rayleigh simply thanked the Society for their gift.—The new Council having been duly elected, the new President (Prof. Greenhill, F.R.S.) called upon Mr. Walker to read his address "On the Influence of Applied on the Progress of Pure Mathematics." The author was asked to print the paper in the Proceedings, on the motion of Mr. A. B. Kempe, F.R.S., seconded by Lord Rayleigh.—The following communications were made:—Spherical harmonics of fractional order, by R. A. Sampson.—Proofs of Steiner's theorem relating to circumscribed and inscribed conics, by Prof. Mathews.—On an algebraic integral of two differential equations, by R. A. Roberts.—Some geometrical constructions, by Oscher Ber (communicated by Prof. Hill).—On the analytical representation of heptagrams, by Prof. L. J. Rogers.

Zoological Society, November 18.—Dr. Mivart, F.R.S., in the chair.—Mr. F. Menteith Ogilvie exhibited and made remarks on a specimen of the Red-headed Flycatcher obtained in Norfolk.—Prof. F. Jeffrey Bell exhibited an example of the Cotton-spinner (*Holothuria nigra*), taken off the west coast of Ireland, and sent for determination by Prof. Herdman.—Mr. G. A. Boulenger exhibited a series of skulls belonging to *Distira cyanocincta* and *Chelone midas*.—Mr. G. A. Boulenger read a paper upon the Reptiles and Batrachians of Barbary (Morocco, Algeria, Tunisia), based chiefly upon the notes and collections made in 1880–84 by M. Fernand Lataste.—A second paper by Mr. G. A. Boulenger contained remarks on the Chinese Alligator.—A communication was read from the Rev. O. P. Cambridge, F.R.S., giving an account of some new species and two new genera of Araneidea, mostly collected in South Africa by the Rev. Nendick Abraham.—Mr. Smith Woodward read a paper on some Upper Cretaceous Fishes of the family Aspidorhynchidæ. He offered a detailed description of *Belonostomus comptoni*, from Brazil, and defined a new genus (*Apateopholis*) from Syria. The latter is remarkable as being the only physostomous fish hitherto described exhibiting a spinous armature of the preoperculum.—Mr. G. C. Champion read a paper on the Heteromerous Coleoptera collected by Mr. Bonny at the Yambuya Camp, Aruwimi Valley.

PARIS.

Academy of Sciences, November 17.—M. Hermite in the chair.—Ed. Phillips, by M. H. Léauté. The deceased mathematician was born at Paris on May 21, 1821, and died on December 14, 1889. An account is given of his many works in mechanics and mathematical physics.—On the name of bronze, by M. Berthelot. The author quotes the following from a work of the time of Charlemagne: "Compositio brandisii: eramen partes II., plumbi parte I., stagni parte I.," that is to say, bronze is composed of two parts of copper, one of lead, and one of tin. This appears to confirm the view that the name of bronze is derived from that of the town of Brundusium, or βρεντήσιον, especially as many bronze vessels have been found marked *ars Brundusinum*.—Remarks on some acoustical sensations provoked by certain quinine salts, by M. Berthelot. The author describes certain humming noises that he hears after the ingestion of lactate.—A Chaldæan astronomical annual used by Ptolemy, by M. J. Oppert. A series of lunar and planetary observations have been found in the British Museum among the cuneiform tablets. These have been deciphered, and prove to be among the oldest and most detailed we possess. The phenomena recorded on them took place in the year 522 B.C., and are described in an exceedingly minute manner. An account is given of the results obtained by an investigation into these cuneiform inscriptions, and their bearing upon the dates of certain events.—On the annual variation in the latitude caused by the differences in refractional effects which result from atmospheric tides, by Dom Lamey. The tidal effect of the sun and moon upon the atmosphere is given as a probable cause of the annual variation in latitude.—Rapid development of a solar prominence, by M. Jules Fényi. The prominence appeared on the western edge of the sun, from heliographic latitude $-20° 13'$ to $-30° 21'$, on October 6, at 1h. 18m. Kalocsa mean time. In about half an hour the eruption had reached a height of 327″—that is, 235,900 kilometres.—On one of M. Picard's theorems, by M. Gustaf Kobb.—Note on the construction of plans from views obtained at elevated points in the atmosphere, by M. A. Laussedat. A method is described by means of which photographic views obtained from balloons may be reduced to plan.—Researches in thermo-electricity, by MM. Chassagny and H. Abraham. The authors have already shown that the electromotive forces of thermo-electric couples, of which the junctions are maintained at 0° and 100° respectively, may be determined to $\frac{1}{1000}$ of their value. They find that the following formula, though not representing their measures with entire accuracy, is sufficient to give the tenth of a degree Centigrade in the interval 0° to 100°. The formula

$$E_0^t = \frac{at + bt^2 + ct^3}{t + 273},$$

where $a = 10^{-3} . 3{\cdot}56604$, $b = 10^{-6} . 8{\cdot}3827$, $c = -10^{-8} . 3{\cdot}265$, t = temperature, and E = electromotive force. The value of E_0 at 100° = 0·0010932 volts with an iron-copper couple. The following is a comparison of observed and calculated results at different temperatures—

Temperature.	Electromotive forces. Observed volts.	Calculated volts.
65°·13	0·0007656	0·0007654
32°·49	0·0004043	0·0004045
15°·48	0·0001981	0·0001980

—On the periodicity of undulatory pressures produced by the combustion of explosives in a closed vase, by M. P. Vieille.

The undulations set up at the extremities of a receiver 1 metre long have been photographically registered by the side of time signals. The extremely accurate results obtained indicate that the method may be used for the study of the phenomena of the propagation of waves in conditions of gaseous condensation and temperature above those as yet investigated.—On the electrical resistance of bismuth in a magnetic field, by M. A. Leduc. The author develops a formula which allows the calculation of the resistance of a wire of bismuth placed in a magnetic field at a certain temperature, in terms of its resistance at 0° outside the field.—On the β-pyrazol-dicarbonic acids, by M. Maquenne. Aldehydes react with dinitrotartaric acid in presence of ammonia, giving rise to monobasic acids which, on heating, form β-pyrazol-dicarbonic acids of the general formula

$$\begin{array}{l} CO_2H-C-N \\ \quad\quad\ \ | \quad\quad\quad \rangle CR. \\ CO_2H-C-NH \end{array}$$

Furfural does not act in the same manner, the body obtained being

$$\begin{array}{l} CO_2H-C(OH)-N=CH-C_4H_3O \\ \quad\quad\quad\ | \\ CO_2H-C(OH)-N=CH-C_4H_3O. \end{array}$$

The sugars with aldehyde reactions give no definite combination with nitrotartaric acid.—On a phenol acid derived from camphor, by M. P. Cazeneuve.—Note upon active amylic derivatives, by M. Philippe A. Guye.—On the saponification of halogen organic compounds, by M. C. Chabrié.—The author forms the fluorides by the sealed tube method, and saponifies these bodies by means of milk of lime, *e.g.*

$$C_2H_4F_2 + Ca(OH)_2 = \underbrace{C_2H_6O_2}_{\text{Glycol}} + CaF_2.$$

A reaction of the halogen compounds with B_2O_3 is also indicated.—On a gaseous antiseptic, its action upon the pyogenous bacteria of the urinary infection, by M. C. Chabrié.—On the fixation of gaseous nitrogen by the Leguminosæ, by MM. Th. Schlœsing and Em. Laurent.—On the microbe of the nodosities of Leguminosæ, by M. Em. Laurent.—On some transitory characters presented by *Chelmo rostratus*, Linn., by M. Léon Vaillant.—On the sexual dimorphism of *Enterocola fulgens*, by M. Eugène Canu.—On the sexual differences of *Lepadogaster bimaculatus*, Flem., by M. Frédéric Guitel.—On the antagonistic molecular forces which are produced in the cellular nucleus, and on the formation of the nucleiform membrane, by M. Ch. Degagny.—On the origin of the terraces (*rideaux*) in Picardy, by M. H. Lasne.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 27.

ROYAL SOCIETY, at 4.30.—On the Homology between Genital Ducts and Nephridia in the Oligochæta: F. E. Beddard.—The Patterns in Thumb and Finger Marks; on their Arrangement into Naturally Distinct Classes, the Permanence of the Papillary Ridges that make them, and the Resemblance of their Classes to Ordinary Genera: F. Galton, F.R.S.—Preliminary Note on the Transplantation and Growth of Mammalian Ova within a Uterine Foster-Mother: W. Heape.—The Conditions of Chemical Change between Nitric Acid and Certain Metals: V. H. Veley.—The Variations of Electromotive Force of Cells consisting of Certain Metals, Platinum, and Nitric Acid: G. J. Burch and V. H. Veley.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Efficiency of Secondary Cells; "On the Chemistry of Secondary Cells: Prof. W. E. Ayrton, F.R.S., and E. W. Smith.

Vernon-Wollaston: George T. Baker.—A Monograph of the Lycænoid Genus Hypochrysops, with Descriptions of New Species: Hamilton H. Druce.—The Life-History of the Hessian Fly: Frederick Enock.

THURSDAY, DECEMBER 4.

LINNEAN SOCIETY, at 8.—On the Genus of Orchid Brownheadia: H. N. Ridley.—On the Botany of Kandahar: J. H. Lace.—Botanical Visit to Auckland Isles: Thos. Kirk.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—On the Volumetric Estimation of Tellurium: Dr. Branner.

FRIDAY, DECEMBER 5.

GEOLOGISTS' ASSOCIATION, at 8.—Report on the Microscopical Examination of some Samples of London Clay from the Excavations for the Widening of Cannon Street Railway Bridge, 1887: C. Davies Sherborn and H. W. Burrows.—A Short Visit to Ingleton and to Filey Brigg (showing how a Dangerous Reef was converted into a Perfect Breakwater by an Ancient Race): Edwin Litchfield.

CONTENTS.

THURSDAY, DECEMBER 4, 1890.

THE COUNTY COUNCILS AND TECHNICAL EDUCATION.

A CONFERENCE will be held to-morrow under the auspices of the National Association for the Promotion of Technical and Secondary Education, which may prove of the greatest importance to the future development of education in this country. The Marquis of Hartington will be in the chair, and representatives of County and County Borough Councils and other Local Authorities working the provisions of the Technical Instruction Act have been invited to meet the Executive Committee of the Association and delegates from its Branches throughout the country, to confer on the best means of utilizing the new fund placed at the disposal of County Councils under the Local Taxation Act of this year for the purpose of education.

It will be remembered that, by the accident of the abandonment of the licensing clauses of the Local Taxation Bill, a sum of about £743,000, the residue of the proceeds of the new beer and spirits duty after defraying the charges for police superannuation, has been allotted to County Councils in England and Wales, with permission to apply the fund to technical education, or, in the case of Wales, to intermediate education under the Welsh Intermediate Education Act. The Scotch share, amounting to another £50,000, may be used for the purpose of the Scotch Technical Schools Act.

A number of reflections are suggested by this unexpected appropriation. Wales is ahead of England and Scotland in the matter, because a more complete Act is in force in the Principality. The Welsh may use the fund to organize their secondary education under public control, while in England such organization, though, as has been pointed out,[1] not impossible, has to be carried out on a far more restricted scale and under more hampering conditions. This is not because the English share of the fund is inadequate, but merely because when the critical moment for the appropriation came it found Wales provided with the necessary machinery, in the shape of the Intermediate Education Act which is unfortunately not yet in force in the rest of the Kingdom. It was too late in the session to build up the requisite machinery for England, so we are compelled to wait.

Had it not been for the passage of the Technical Instruction Act of 1889, which, as will be remembered, was fiercely contested at the time by many of the more extreme educational partisans, there would have been no machinery at all in England for the utilization of the new fund for education, and the whole would doubtless have been allotted to other purposes, such as reduction of rates. As it is, the fund can be administered under the provisions of that Act, incomplete as it is, until it is duly amended by the Bill of which Sir Henry Roscoe has already given notice, and by the extension to England, under a somewhat modified form, of the Welsh Intermediate Education Act. Thus, had it not been for the previous passage of a confessedly imperfect measure, the greatest chance yet offered for the organization of secondary education would have been missed altogether. We hope this fact will be remembered when heated advocates of one line or other of educational policy are again tempted to forget that "half a loaf is better than no bread." Get public supervision of higher education recognized in an Act of Parliament, and all the rest will surely follow. The Act may be imperfect; parts of it may be bad; but he is a pedant who refuses it on that ground. The Act will be amended as necessity arises; new powers of control will be acquired when any power of control has been once conceded. The new Act gives increased facilities for the organization of education to various parts of the Kingdom in precise proportion to the powers already possessed. "To him that hath shall be given," in education as in other matters.

So much for the Act. The next question that arises is its administration by the local authorities, who, it is to be observed, have power to devote all or any part of the fund to education, and of course to use the rest for the relief of rates. It must be admitted that it is a great temptation, to some County Councils at least, to take advantage of their undoubted right to use the fund otherwise than Parliament intended; but it is a temptation which should be resisted if only for the reason that the renewal of the grant next year may largely depend on the use which can be shown to have been made of it by local authorities. It would be suicidal policy, even for the strictest friend of the ratepayer, to clutch the money this year for the relief of rates, and thus to lose permanently a grant which will be sorely needed before long in order to meet the new charges which, as Mr. Goschen hinted, are likely to be put upon local authorities with respect to agricultural and intermediate education.

So far as the matter has yet come before County Councils, there is no cause for discouragement. At least nine counties have already determined to use the whole or part of the money for technical education; others have appointed committees to inquire into the whole question. We hope that the result of the Conference which is announced will be to decide many wavering Councils to take the same course.

There will be plenty for the Conference to discuss. The work of organizing technical education is new to County Councillors, and many of them are still quite in the dark on many points. Moreover, practical difficulties have arisen in some districts in the working of the Act, on which it will be useful to compare notes. We have received a copy of the provisional agenda, by which we see that among other things the meeting will discuss the nature of the preliminary proceedings which should be taken by County Councils which are desirous of assisting education out of the new fund. This is an important question. Should the Councils simply pass a resolution inviting applications for assistance, and then judge among the various qualified institutions which send in claims? Or should they institute an inquiry into the state of education in their districts, and on the results of that inquiry formulate a comprehensive scheme? Should the money be devoted chiefly to the assistance and development of existing institutions? Or should the Councils initiate schools of their own under the general powers conferred by the Act? On matters like this many

[1] See "Suggestions to County Councils" (National Association for the Promotion of Technical and Secondary Education, 14 Dean's Yard).

Councils are doubtless waiting for a lead such as they may obtain at the Conference. Meanwhile we may commend to their attention the carefully drawn report just presented to the Shropshire County Council by the Technical Instruction Committee of that Council, as a model in many ways of what such a report should be.

The Conference will also discuss the modes in which the fund may be divided among the non-county boroughs and sanitary districts within the county. This again, is a debatable question. Should the basis of the allotment be rateable value, or population, or existing local effort? How far should the convenience and needs of the county as a whole be exclusively consulted in the scheme, independently of the wishes or claims of particular localities? Clearly the Act gives no legal claim to a non-county borough on any particular proportion of the money, though the County Council may, if it please, act through these minor authorities in the distribution. The question is eminently one on which light will be thrown by a friendly conference.

The third point for discussion is the amendment of the Technical Instruction Act. Certain difficulties have arisen in the administration of the Act, which may be removed without raising controversies. For example, many Councils wish to aid agricultural education by founding or assisting agricultural schools in county boroughs in their district. But this they may not do, for the county boroughs are outside their jurisdiction; while the county boroughs themselves are not likely to do the work, since it will, as a rule, be useless to their own inhabitants. Other points, such as the question of the provision of scholarships, especially to schools outside the counties, have been called in question, and need settlement.

The fourth subject on the agenda is the most important of all; viz. the best mode of assisting intermediate and agricultural education. It is hardly to be expected that the members of the Conference will succeed in evolving a complete plan; but they will do a great service if they demand, with no uncertain voice, the extension to England of a measure based on that which is working so admirably in Wales. Meanwhile, the question of the best mode of assisting intermediate education depends very greatly on the chance of the future renewal of the grant. We look to Lord Hartington to give an assurance that there is no possibility of the diversion of any part of the new fund by the Government to other purposes than technical and secondary education.

DREYER'S LIFE OF TYCHO BRAHE.

Tycho Brahe: a Picture of Scientific Life and Work in the Sixteenth Century. By J. L. E. Dreyer, Ph.D., F.R.A.S. (Edinburgh: A. and C. Black, 1890.)

THE time had evidently come for the publication of an adequate account of the life and work of the great Danish astronomer. Popular presentments of the first, and partial studies relating to the second, there have been, it is true, in more languages than one; but Gassendi's was, until now, the only scientific biography of Tycho Brahe; and numerous documents, inedited and inaccessible in 1654, have since been brought to light, clearing up much that was obscure, supplementing meagre with full information, and thus rendering possible the virtually complete narrative now given to the public by Dr. Dreyer. That unstinted pains were bestowed upon his task is obvious from the manner of its accomplishment; and he was equipped for it with a combination, desirable rather than usual, of linguistic, historical, and scientific attainments. Indeed, at times, superabundant information is afforded; the wealth of details tends to congestion; the essential does not decisively enough maintain its supremacy over the superfluous. The book is none the less a most valuable contribution to the history of mediæval astronomy; it is creditably exempt from slips and inaccuracies of memory, pen, or print; abounds with bibliographical knowledge and indications; and—not its least merit—is furnished with a highly serviceable index. It portrays, moreover, with perfect candour, yet full comprehension and sympathy, a vigorous and picturesque individuality.

Judgment in forming, and persistence in holding to, a large and definite purpose, rather than surpassing intellectual ability, caused Tycho Brahe to tower above his scientific contemporaries. Wittich—to say nothing of Viète and Harriot—was his superior in mathematics; he could lay no claim to the inventive ingenuity of Joost Bürgi; his system of the world was less plausible than that of the uncouth Reymers. But he saw clearly what was indispensable to the progress of astronomy, and by the undaunted energy of his efforts to supply it, raised himself to the high level of his great undertaking.

Until observations were begun at Uraniborg, the astronomy of the ancients, as Dr. Dreyer says with truth, reigned practically undisturbed. A speculative impulse of incalculable importance had indeed been given by the promulgation of the Copernican doctrine; but

"No advance had been made in the knowledge of the positions of the fixed stars, those stations in the sky by means of which the motions of the planets had to be followed; the value of almost every astronomical quantity had to be borrowed from Ptolemy, if we except a few which had been redetermined by the Arabs. No advance had been made in the knowledge of the moon's motion, so important for navigation, nor in the knowledge of the nature of the planetary orbits, the uniform circular motion being still thought not only the most perfect, but also the only possible one for the planets to pursue. Whether people believed the planets to move round the earth or round the sun, the complicated machinery of the ancients had to be employed in computing their motions, and, crude as the instruments in use were, they were more than sufficient to show that the best planetary tables could not foretell the positions of the planets with anything like the desirable accuracy.

"No astronomer had yet made up his mind to take nothing for granted on the authority of the ancients, but to determine everything himself. Nobody had perceived that the answers to the many questions which were perplexing astronomers could only be given by the heavens, but that the answers would be forthcoming only if the heavens were properly interrogated by means of improved instruments capable of determining every astronomical quantity anew by systematic observations. The necessity of doing this was at an early age perceived by Tycho Brahe. . . . By his labours he supplied a sure foundation for modern astronomy, and gave his great successor, Kepler, the means of completing the work commenced by Copernicus" ("Tycho Brahe," p. 9).

On August 21, 1560, the young Scanian noble, then a thirteen-year old student at the University of Copenhagen, watched the moon, punctual to prediction, obscure a few digits of the sun's face, and was impressed with it "as something divine that men could know the motions of the stars so accurately that they could long before foretell their places and relative positions." Thenceforward all other pursuits were with him secondary to that of training himself for an astronomer. "Was ein Haken werden will, krümmt sich bei Zeiten." But the career was regarded as compromising to the dignity of his birth, and his uncle sent him to Leipzig in charge of a tutor—the excellent Anders Vedel—whose chief business it was to interpose between him and the heavens. In vain; while Vedel was asleep, Tycho studied his Almegist, learned the constellations from a little globe the size of his fist, and, on the occasion of an important conjunction of Jupiter and Saturn, made his first recorded observation (August 17, 1564) with no other instrument than an ordinary pair of compasses. In the following year he procured a "radius," or "cross-staff," subdivided by the newly invented method of transversals, and gave, in his table of corrections to the results obtained with it, "the first indication of that eminently practical talent which was, in the course of years, to guide the art of observing into the paths in which modern observers have followed" (Dreyer, *l.c.*, p. 20). By this time, too, the intuition had come to him that the planets themselves, consulted with prolonged and patient vigilance, could alone impart trustworthy intelligence as to the system of their motions; and thus, in the mind of a boy of seventeen, the "restoration" of the prehistoric science *par excellence* was conceived and determined upon.

Other interests, however, supervened; and chemical, or, rather, alchemistic, researches might have continued to absorb the attention of one capable of better things, had not his vocation to astronomy been renewed under sanction of the portent (as it were) of the stellar outburst in Cassiopeia. Tycho hesitated no longer, but waited the propitious moment, and sought the appropriate scene for the commencement of his life's labours. He had fixed upon Basle; but the King of Denmark, Frederick II., anticipated his removal thither by the offer of an island-domain in the Sound, together with funds for the erection upon it of suitable buildings.

Their nature and plan are illustrated, both graphically and descriptively, in the work before us. Suffice it here to say that their cost was commensurate with their splendour, and could only have been defrayed by Royal munificence. Yet, after its withdrawal by Christian IV., private means might have sufficed to maintain what they were inadequate to create; for the "Phœnix of astronomers" (as Kepler designated him) was still a comparatively rich man when, rather in disgust than from necessity, he forsook Uraniborg in April 1597. Nor was he free from blame in the transactions which led to his purely voluntary exile. His government of Hveen was nearly absolute, and somewhat arbitrary; his dealings with his tenants, there and elsewhere, were often harsh and tyrannical; he could scarcely be brought, by repeated Royal admonitions, to comply with the conditions of the various grants made to him; and his arrogant bearing made enemies who did not fail to accentuate his shortcomings. A tradition more honourable to him ascribes, it is true, a share in bringing about his disgrace to the King's physician, Peder Sörensen, whose jealousy is said to have been excited by Tycho's unpaid practice of medicine; but Dr. Dreyer saddles the chief responsibility upon the Chancellor Friis, interested, possibly, both through motives of public economy and of private hostility, in the fall of a costly and unsubmissive subject of the Crown. In short, Sir Roger de Coverley's cautious dictum, that "much might be said on both sides," may serve to convey the equitable judgment of posterity as to affairs at Hveen and their lamentable upshot.

Its worst result was in the waste of valuable time. Four years were virtually curtailed by it from the great astronomer's effective career. Yet one compensatory circumstance attended the disaster. Tycho's presence attracted Kepler to Prague; and their connection, formed just at the right moment for progress, put the younger man in possession of a store of facts, from the co-ordination of which he was enabled to deduce the laws constituting the fit epilogue to the work of Copernicus, the indispensable preface to that of Newton.

The results of Tycho's activity during upwards of twenty years at Uraniborg, were summed up by himself as follows:—An improved solar theory; the detection of the third inequality, or *variation*, in the moon's motion, as well as of fluctuations both in the inclination of the lunar orbit, and in the shifting of the nodes; the accurate ascertainment of the places of one thousand fixed stars; the dismissal from astronomy of the supposed "trepidation" of the equinoxes; the collection of a vast mass of materials for the revision of planetary tables; the supply of ample proof that comets are trans-lunar bodies (Dreyer, *l.c.*, p. 262). He might have added the discovery of the lunar annual equation (almost simultaneously perceived necessary by Kepler, as Dr. Dreyer points out); the employment of systematic corrections for refraction; and observations, continuous and exact, of the "new star" of 1572.

Theory was not Tycho's strong point. He attached much more importance than it deserved to his system of the world, which he vainly hoped would outlive himself; nor was he endowed with a penetrating insight into the significance of the phenomena observed by him with such marvellous skill. This may be estimated from the probable errors of his positions for nine standard stars, amounting, as compared with the best modern results, to $\pm 24''$ in right ascension, $\pm 26''$ in declination (Dreyer, *l.c.*, p. 351). His absolute right ascensions were derived from the longitude of the sun through Venus as an intermediate link; his declinations were directly measured. When it is remembered that he was destitute of any kind of optical aid, that his graduated instruments must have been, judged by modern criteria, intolerably defective, that he knew nothing of the effects of aberration and nutation, and commanded only a rough value for precession, the degree of accuracy thus attained must excite our wondering admiration. It should be added that the utter untrustworthiness of his clocks precluded him from the determination of relative places by the easy method of transits.

The frontispiece of the book under review is taken from a portrait of Tycho Brahe painted at Rostock in 1597, and reproduced some few years since in these pages (NATURE, vol. xv. p. 406). Purchased by the Earl of Crawford in 1881, it formed part of his generous gift to the Royal Observatory, Edinburgh. The illustrations in the body of the work, consisting of plans and elevations of Uraniborg, portrayals of the instruments, later residences, and tomb, of its whilom inmate, are both interesting and well executed. The last represents the figure carved in red marble on the monument to Tycho Brahe in the Teynkirche at Prague. Its martial aspect corresponds with the feudal pomp amid which his remains were borne to their last resting-place. Not recumbent, though sleeping, he stands erect, clad in full armour, a plumed helmet on one side, an emblazoned shield on the other, a sword grasped in his left hand. Nothing recalls the genuine quality of his life except the globe upon which his right hand rests, and the inscription from his demolished observatory, "Nec fasces nec opes, sola artis sceptra perennant." A. M. CLERKE.

TWO NEW PSYCHOLOGIES.

A New Psychology: an Aim at Universal Science. By the Rev. George Jamieson, D.D., &c. (Edinburgh: Andrew Elliott, 1890.)

Hand-book of Psychology: Senses and Intellect. By Prof. J. M. Baldwin, M.A., Ph.D. (London: Macmillan and Co., 1890.)

WE are quite ready to allow Dr. Jamieson that, as he claims in his preface, his work is strictly original. We do not think, however, that he need fear that, because it emanates from a clergyman, it will be any the less attentively considered by any competent persons. The reasonings and speculations, in another branch of science, of Dean Conybeare, of Prof. Sedgwick, of Dr. Bonney, or of Mr. Osmond Fisher, have, so far as we can judge, in no wise suffered from this cause. And if there were any value in the reasonings and speculations of Dr. Jamieson, in the realm of psychology and philosophy, they would be as readily and thankfully accepted as those of Bishop Berkeley or Dr. Mansell. But, in truth, however well grounded in theology, Dr. Jamieson's little book gives abundant evidence that he is not very thoroughly grounded in more mundane branches of science.

It is impossible to summarize briefly this "new psychology." We therefore content ourselves with giving two or three extracts which we consider representative, and must then leave such of our readers as aspire to fuller knowledge to worry through the book for themselves.

"It is of enormous moment," we are told, "to understand what it is that really constitutes the soul, as well as to apprehend under what circumstances the soul is constituted. We know of no other substance, as absolute and eternal, than that of Ether. It is absolute in two important respects, *first*, as positive and conditioned, and *second*, as negative and unconditioned."

"If it holds good, as a fact throughout all nature, that material structures have their conditions represented by an immediate encompassment of their delineation in Ether, and if it holds equally good, that in the animal frame generally, and especially in man as the highest exemplification, there is a nerve system in the body known as the 'sympathetic,' and carrying its affections, *i.e.* conducting the states of the living body to one single pole or axis, as the terminal of concentration,—as the pivot whereon the assembled conditions of animal states are manifested, what follows in the first place, as the necessary result of this concentration? Why, surely this, that precise analogy with all that we know, as express revelations in our experience must, in this particular case, be the actual outcome of an Etherial Image or representation of this complex animal self-hood."

"The very fact of our discovery that the pure Etherial Medium, as spirit-substance, is ever present as the fundamental mainspring of operation, in the linking together of conditions in the material world, opens the door of apprehension for us to comprehend the inter-workings of Brain, in producing the phenomena of Mind, as manifested in the Soul or Ego of each personality."

A very different book is the first instalment of Prof. Baldwin's "Hand-book of Psychology," of which a second and revised edition is before us. Well arranged, carefully thought out, clearly and tersely written, it will be welcomed in this country as it has been welcomed in America. That it views psychology from a standpoint somewhat different from that which Mr. Sully takes up in his "Outlines" will render it none the less acceptable to English students.

An interesting and important section is devoted to "consciousness and the unconscious," and Prof. Baldwin brings out very clearly the difficulties that attend the view that mental phenomena may be unconscious. He notes that it is often the case that an association between states of mind is accomplished without conscious links of connection, and that consequently the links of connection must be unconscious. He thinks it unsatisfactory, however, to say that the unconscious links are states of mind. "The missing links in broken chains of associations," he contends, "may be supplied from dynamic connections in the cerebral substance." But there are many people who think that it is as inconvenient as it is unphilosophical to dodge backwards and forwards from the brain to the mind. Either mental states are of a different phenomenal order from physical states or they are not. If they are not, let us at once say that just as the lachrymal gland produces tears so does the brain produce consciousness. If they are, then let us, so far as is possible, avoid hopping backwards and forwards from one to the other. The fact is, this question cannot be discussed without touching on the philosophical basis of psychology. Our own opinion is that we should be aided here by that most reprehensible procedure—the coinage of a new term. Believing, as we do, that mind never has been, and never could be, evolved from matter, the question arises, From what, then, have mental states (psychoses) been evolved? If a similar question be asked with regard to molecular vibrations in the brain (neuroses), the answer is not difficult. Complex neuroses have been evolved from less complex neuroses; these from simple neuroses; these again from organic modes of motion which can no longer be called neuroses at all; and these perchance, once more, from modes of motion which can no longer be called organic. But in the case of psychoses, from what have they been evolved? Complex psychoses have been evolved from less complex psychoses; these from simple psychoses; and these, again, from—what? From other and simpler modes of—something which answers on the subjective side to the organic modes of motion. For this we might use some such term as *metakinesis*. Neuroses are kinetic manifestations; states of consciousness are metakinetic manifestations. But, as neuroses are evolved from kinetic states (kineses) of a lower order, so have psychoses been evolved from metakinetic states (metakineses) of a lower order. According to this view, every mode of organic or neural kinesis has its concomitant mode of metakinesis, and, when the kinetic manifestations assume the form and intensity of neuroses in certain parts of the human brain, the metakinetic manifestations assume the form of human consciousness. Instead, therefore, of jumping across, with Prof. Baldwin, from psychical to physiological states, we would suggest that, from the point of view of psychology, the intermediate states are metakineses, which do not reach a sufficient intensity or complexity to appear in consciousness as states of mind. They are not unconscious states of consciousness, but they belong to the same phenomenal order as consciousness.

In his interesting discussion of the perception of space, Prof. Baldwin says:—

"Two general theories of space perception are held by psychologists, and under them may be classified the various attempts made to explain the origin of this idea. These are the *nativist* and the *empirical* theories. Empiricists hold that presentation of extension (and time) are derived through experience from elements which have not the spacial (and temporal) form. On the other hand, nativists maintain that space and time presentations cannot take their origin in data of consciousness which are simply intensive; consequently that these presentations are primitive data of knowledge, native, innate. In other words, the empiricist asserts the reducibility of presentations of space and time, and the nativist asserts their irreducibility."

Now here it seems to us that, if the empiricist claims to reduce the perception of space to sense-impressions, he is manifestly in error; and that, if the nativist bases his contention on the fact that there are over and above sense-impressions, impressions of relation, he is on firm ground. But it is questionable whether he can carry his claim much further.

Prof. Baldwin has a short but important chapter on illusions. We are unable entirely to agree with him in his treatment of the subject. Speaking of illusion proper, he says:—

"At the outset we find ourselves face to face with a whole class of experiences, in which one mental state is *taken for another*. There are, really, two images involved —one, the rightful image, the presentation, as ordinarily aroused by the stimulus experienced, say the sound of the clock; the other, the image of something different, formed within the domain of the same sense-quality, and usually prominent in consciousness before the time of the illusion, as the alarm of fire, into which the striking of the clock is interpreted."

This does not seem to us altogether satisfactory. Prof. Baldwin, at an earlier stage of his thesis, well brings out the fact that a percept is a mental construction formed at the bidding of a stimulus or sense-impression. Now, an illusion is simply a false and erroneous mental construction. If, to take another of Prof. Baldwin's examples, a man in the half light takes a tree for an Indian, or if a nervous old lady takes a grey donkey for a ghost, at the time of presentation the tree image and the donkey image have no existence. There is one image in each case—that involved in the false and erroneous mental construction. The difference between a true percept and an illusive percept is that the one is confirmable by the process of verification on further examination, and the other is not.

We have left ourselves no space to consider Mr. Baldwin's treatment of reason.

"The rational function," he says, "is contrasted with the apperceptive function in the absence of the element of process, which constitutes the essential nature of the latter. Apperception is a process, through which the material of acquisition passes in preparation for the higher uses of mind. Reason, on the contrary, is not a process, as the more special term, intuition, given to it implies. It conditions and underlies all mental processes. It is the nature of mind itself as it reveals itself in consciousness."

On this somewhat might be said. But we have already said enough to show that we regard the work as a valuable and stimulating hand-book of psychology, so far as the subject is treated in this instalment. C. LL. M.

THE MYOLOGY OF THE RAVEN.

The Myology of the Raven (*Corvus corax sinuatus*): *A Guide to the Study of the Muscular System in Birds*. By R. W. Shufeldt. (London: Macmillan and Co., 1890.)

WITH the exception of the brief descriptions in several of our zootomical text-books of certain of the muscles in birds, there has been up to the present time no special manual treating of this subject in detail. The student of avian myology has therefore had some difficulty in obtaining the requisite directions for his work, more especially if the advantages of a scientific library were not within his reach. Such works as those of Gadow in Bronn's "Thierreich," and of Fürbringer in his monumental "Untersuchungen zur Morphologie und Systematik der Vögel," besides being written in German, are not easily obtainable by the greater number of workers. The present book, from the fertile pen of Dr. Shufeldt, fills up this important gap in a highly satisfactory manner.

At first sight, it might appear an objection that Dr. Shufeldt has chosen such a rare bird as the raven as the subject of his work. But as other species of *Corvidæ* are so easily obtainable almost everywhere, it is perhaps even an advantage that the student in using the book cannot follow out every detail slavishly: by making use of some allied form, which agrees in the main, but differs in detail, from the Raven, he will learn more, and at the same time gain more self-reliance.

Though following, as regards nomenclature, the authority of Owen, Carus, A. Milne-Edwards, Huxley, Garrod, Forbes, Selenka, Coues, Fürbringer, Gadow, and others, the author has in doubtful cases introduced names of his own making, and has quoted very freely from Gadow (Bronn's "Thierreich"), whose synonymy is given fully in footnotes throughout the work. These notes indicate very plainly that we have as yet by no means arrived at a satisfactory knowledge of the muscular system in the Vertebrata, and that our existing nomenclature is far from perfect. It is to be hoped that the present work will aid in laying the foundations of a more satisfactory system, and will help to point out the gaps in our knowledge as regards the muscles in many important types of birds. The author does not entirely confine himself to a description of the raven: other types are referred to in special cases when certain muscles are not represented in the latter; and comparisons are given in many cases with other forms—mammals as well as birds.[1]

Though acknowledging the importance of the question of nerve-supply in helping to determine the homologies of muscles, the author by no means considers this to be an infallible guide; for the representative of the same muscle in various vertebrates is not always supplied by the same nerve. He also quotes some remarks of his own from a previous paper (referred to in the text as No. 124 in the Bibliography, instead of No. 121), with regard to the value of muscles in classification, which are of importance in helping to relegate the muscular system of birds to its proper subordinate position in taxonomy. While fully recognizing the value of Garrod's work in this field, it must be agreed that his myological formulæ only represent one set of characters, which must be taken in conjunction with all others if they are to be of any value in classification.

The various groups of muscles are treated in order, beginning with the dermal system, and a chapter is devoted to each main set. In each group, directions are given how to proceed with the dissection. The figures, of which there are 76, are on the whole excellent, and with few exceptions are original: they represent the different parts of the skeleton, showing the origins and insertions of the muscles, as well as dissections of the muscles themselves. A copious bibliography and index are given at the end of the book.

It is almost impossible to comment on the details of the work without having first made use of it practically. But we can congratulate Dr. Shufeldt on the production of an original and well-arranged text-book, the result of much patient labour in collecting and dissecting, and careful thought in arrangement. The volume will appeal especially to ornithologists, as well as to students of comparative anatomy.

OUR BOOK SHELF.

Chemical Arithmetic. Part I. By W. Dittmar, LL.D., F.R.SS. Lond. and Edin. (Glasgow: William Hodge and Co., 1890.)

THIS volume is not a mere collection of tables extracted from the numerous books which deal with this subject, but is a good and trustworthy piece of work, with no lack of originality about it, and contains the mathematical auxiliaries and both chemical and physical constants which a chemist needs "in the ordinary routine of his laboratory work." Some of the tables contain the results of the author's work, and others have received slight alterations, been put in more convenient forms, and brought up to date.

Indexed tables of three-, four-, and five-place logarithms are given, and following these will be found formula values, F, of a number of substances and radicals and their logarithms, analytical factors and their logarithms, gas volumetric determinations, metric and British systems of units, &c. Near the end there is represented in diagrammatic form a double thermometer scale, with Fahrenheit degrees on one side and Centigrade on the other, ranging from $-148°$ F. to $+392°$ F., by which a result in degrees Fahrenheit can be directly stated in terms of the Centigrade, or *vice versâ*. Throughout the book the author seems to have taken the utmost pains to eliminate all errors that are likely to be made in a work of this sort, and by this means he has placed before the scientific as well as before the technical chemist a useful and trustworthy reference book.

Dictionary of the Language of the Micmac Indians. By Rev. Silas Tertius Rand, D.D., LL.D. (Halifax, N.S.: Nova Scotia Printing Company, 1888.)

THE Micmac Indians are an aboriginal tribe of the Algonquin family, residing in Nova Scotia, New Brunswick, Prince Edward Island, Cape Breton, and Newfoundland. The late Dr. Rand, the compiler of the present work, laboured among them as a missionary for more than forty years. He was a man of great learning and ability, and soon not only mastered the language of the Micmacs, but devoted himself to the task of reducing it to writing. He also translated into it the New Testament and portions of the Old Testament, and claimed to have collected and arranged in alphabetical order no fewer than 40,000 Micmac words. His dictionary consists of a Micmac-English and an English-Micmac part. Greatly to their credit, the Dominion Government paid for the manuscript of both parts, and now they have issued the English-Micmac section of the work. The other section must necessarily be of more scientific interest, but this volume may be of greater practical value. Even from the scientific standpoint, it cannot fail to be of service to philologists. Most students will probably be surprised to find how highly developed a language the Micmac is. It was strongly admired by Dr. Rand, who went so far as to say that in various important particulars it would not suffer from "a comparison with any of the most learned and polished languages of the world."

Elementary Manual of Magnetism and Electricity. By Andrew Jamieson, M.Inst.C.E. (London: Charles Griffin and Co., 1890.)

THIS work is arranged in the form of a series of lectures, and covers the ground laid down in the syllabus for the elementary stage of the Science and Art Department examinations. The subject is divided into three distinct parts. Part I. treats of magnetism; Part II. of electromagnetism and current electricity, under the general heading voltaic electricity; while Part III. deals with frictional electricity. At the conclusion of each lecture a number of examples is given, and in many cases a test question, with the answer. By no means less important are the appendices to each part, in which students will find all the necessary information for making experimental apparatus and for conducting experiments with them. Throughout the book the author has made many references to the practical applications of these experimental facts, such as telegraphy, telephony, electric lighting, &c., and has given some very good illustrations and diagrams, in which the various points for which they were intended have been brought out effectively.

In the present manual, only an elementary knowledge of arithmetic is required in order to follow the expositions; but in the advanced text-book, which the author informs us is now in preparation, and to which the present volume will form an introduction, an elementary knowledge of mathematics will be assumed.

[1] Frequent references are made to Owen's description of the muscles of Apteryx. Quite recently T. J. Parker has shown that some eleven or twelve muscles are present in the vestigial wing of this form in addition to those described by Owen.

The Stereoscopic Manual. By W. I. Chadwick. (London: John Heywood, 1890.)

IN this little manual the author takes up the case of the once popular instrument the stereoscope, and shows how by means of recent improvements very good results may be obtained. The first two chapters are devoted to the subject of binocular vision and the theory of the stereoscope; then follow some practical points concerning the production of stereoscopic photographs. To enable the stereoscopic camera to be used as an ordinary camera, the author has devised a spring roller and curtain division that can be removed in an instant when single views are required, and replaced as quickly for stereoscopic work again. In the remaining part of the book are short chapters on the best lenses to use, transposing and mounting of slides, transparencies on glass, and combination printing. Throughout the manual the author has given enough information as regards the mode of procedure to enable one to obtain a finished picture, so that for amateurs and others who are thinking of taking up this branch of photography the book should prove a most useful and efficient guide.

Astronomy: Sun, Moon, and Stars, &c. By William Durham, F.R.S.E. (Edinburgh: A. and C. Black, 1890.)

IN this little work we have a clear and interesting account of the more important facts connected with the science of astronomy. It treats of the sun and moon, the earth, stars, nebulæ, planets, astronomical speculations—such as those relating to the formation of the heavenly bodies—concluding with chapters on the tides, light and spectrum analysis. Perhaps an improvement might be made in the order in which the chapters are arranged. The first two deal with some bodies in the solar system—namely, the sun, moon, and earth; the next one treats of the stars, nebulæ, &c.; while in the fourth we are suddenly brought back to the solar system in connection with the planets.

The information is well up to date, and is presented in simple and plain language. The author gives a very good idea of the present general knowledge on these subjects, without entering into details which would tend to puzzle the reader for whom works of this kind are written.

The Life Story of Our Earth. By N. D'Anvers. (London: George Philip and Son, 1890.)
The Story of Early Man. By N. D'Anvers. (Same Publishers.)

THESE volumes belong to the "Science Ladders" series, which consists of simple reading-books in elementary science for the young. The author has selected his facts with care, and presents them in a plain straightforward style, well adapted for the purpose for which the books have been prepared. There are many illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Great Mogul's Diamond and the Koh-i-nur.

IN the review of my edition of "Tavernier's Travels" which was published in NATURE (vol. xli., p. 313), the writer having commented, with approval, on the arguments advanced by me in favour of the hypothesis that the Koh-i-nur can be identified with the Mogul's diamond, proceeds to say:—

"But as regards the identity of the Koh-i-nur and the Mogul diamond, there remains one objection which, as it appears to us, Mr. Ball has hardly adequately disposed of. If Tavernier's figure, as reproduced by Mr. Ball, represents at all faithfully the general form and especially the height of the Mogul diamond, it is difficult to see how a comparatively flat stone like the Koh-i-nur could have been obtained from it without a much greater reduction of its weight than the 82 carats which are all that his data admit of. The lateral dimensions of the two stones accord fairly enough, so that any reduction of Tavernier's figured stone, to bring it down to the required size, could be effected only by diminishing its height; in which case it would hardly correspond to his description of its form as that of an egg cut in two. The question can only be fairly tested by the weighment of a model constructed, as nearly as possible, in accordance with Tavernier's figure, and of such lateral dimensions as to be capable of including the Koh-i-nur. It may be found that such a model, of the specific gravity of the diamond, would be found much to exceed Tavernier's reported weight of the stone, in which case the importance of his figure as an item of evidence would be invalidated."

This very point suggested itself to me also for investigation long ago; but hitherto from want of a suitable model I postponed undertaking it. Recently I have obtained a glass model, which coincides, exactly, with Tavernier's figure; another model, of which an example has been examined by me, is too small in diameter. These models are included in the well-known collections of glass models of famous diamonds; from them the often faulty figures given in works on precious stones have generally been drawn.

On submitting the first-mentioned model to weighment, it proves to represent a diamond not of 279·56 Florentine carats, *i.e.* 268·38 English carats, as it should; but it represents a diamond of 437·9 carats—in other words, it includes an excess of 169·52 carats. It is therefore far too large, and if we consider in what respect it is most likely to be defective it is surely in the height and general mass of the stone. Tavernier was not an artist—he admits as much himself; but he probably measured the diameter of the stone accurately, though his sketch or diagram was otherwise exaggerated. Out of a flatter stone with the same diameter, the Koh-i-nur might easily have been cleaved, with a loss of about 82 carats (268·38–186·6). And the original might, to some extent, have resembled, as he describes it, an egg cut in two, not across, perhaps, but longitudinally.

It may be asked, Can the true form of the Mogul's diamond be approximately reconstructed? I think it can. By taking an authentic model of the Koh-i-nur, as it was when brought to England, and by replacing symmetrically on the cleaved surfaces and upon the upper portion of the stone an amount of material equivalent altogether to 82 carats, the result would give, I venture to believe, a very close approximation to the form of the Mogul's diamond as it was when seen and described by Tavernier.

Many collateral facts which have come to my knowledge since I wrote on this subject, but which I cannot trespass so far on your space as to detail here, tend to confirm the hypothesis that the Koh-i-nur is identical with the Mogul's diamond—less by certain portions which were demonstrably removed by cleavage, after the original cutting.

It may be added that the models of some of the other famous stones in the collections above referred to also prove to be very inaccurate in their dimensions; none of them, however, are so outrageously exaggerated as that which professes to represent the Mogul's diamond.

Little wonder is it, therefore, that some writers should assert that such a stone no longer exists, for it never did exist in the form and of the size represented by these models, and by the figures prepared from them for works on precious stones.

V. BALL.

Science and Art Museum, Dublin, November 29.

Pectination.

IN looking over a collection of skins early in the present year, I was struck by the recurrence of the pectination of the claw of the third digit in many different orders of birds; such a structure occurring among the owls, nightjars, herons, and gannets. The fact is, of course, well known; but the popular explanation of it—that the serration is useful in enabling the bird to hold its prey (fish, &c.) more securely—cannot be correct: first, because the serration is small in extent, and only present in a single claw; and secondly, because it is at the side, and not on the under surface, of that claw. At the same time, it is too widespread and well-marked a characteristic not to be functional.

The pectination seems to attain its greatest development in the nightjars; and it has been said that these birds utilize it for the purpose of cleaning their mouth-bristles. But the bristles and the pectination do not by any means always occur together, even among the nightjars; while many other birds (*e.g.* barbets) have the former without the serration.

In order to investigate the point, I procured a young common heron (*Ardea cinerea* ♂?) in June last, and have had the bird under more or less close observation from that time until the middle of October. It fed freely for the most part, and continued healthy during the whole of this time. Its food, whether living or dead, and whether taken from water or from the ground, was never touched at all by the feet. The only use to which the serrated claw was put, that I could observe, was that of scratching the cheeks and throat. In this action—which occurred most frequently after a meal—the two other front toes were curved down, so as to leave the middle claw free.

It is, however, the case that other birds, in which the pectination is absent, use the middle claw alone in scratching. Nor would the presence of this peculiarity seem to give any great advantage to its possessor in this connection, owing to its lateral position. I fear, therefore, that I can claim to have done no more than disprove experimentally what hardly needed disproving—the popular theory alluded to above.

Inselstrasse 13, Leipzig, Nov. 25. E. B. Titchener.

The Common Sole.

The correction from Mr. Green, H.M. Inspector of Irish Fisheries, which is published in Nature of November 20 (p. 56), and which announces that the specimens he at first believed to be the young of the common sole proved to be really the young of *Pleuronectes cynoglossus*, is one more instance of the great importance of specific identification in the investigation of fishery problems. This was a mistake not merely as to the species, but as to the genus of the specimens in question. And yet it is by no means difficult, after a little experience, to distinguish the genus *Solea* at any stage of development from all other genera of *Pleuronectidæ*. It is much more difficult to distinguish from one another the various species of Gadus in their early stages. But in order to ascertain the life-history of the various species of sea-fish used as food, we must trace each with absolute certainty from one environment to another through the successive stages of its existence.

It is natural enough that the young fry of *Pleuronectes cynoglossus* should be found in deep water. The adult of this species has an exceedingly wide bathymetrical range. It is found in abundance on our ordinary trawling grounds in the North Sea at 15 to 30 fathoms, and I have taken it in numbers in the Firth of Clyde. In the same region which Mr. Green investigated, Mr. G. C. Bourne found it at 70 fathoms and at 200 fathoms. The Norwegian North Atlantic Expedition found it at 125 to 150 fathoms off the Lofoten Islands, while on the North American side of the Atlantic it has been taken at 120, 263, 395, 603, and 732 fathoms. On the other hand, *Solea vulgaris* has never been found at a much greater depth than 60 fathoms.

Seeing that I have found young soles immediately after metamorphosis between tide-marks, it would have been extremely surprising if the next stage only occurred beyond 50 fathoms. Most probably the fry of the sole will be found pretty uniformly distributed over the grounds where the adults live. After the stage I have mentioned, they are not found in shallow water. I have some evidence that the above suggestion is true, for specimens from 3 to 6 inches in length have been recorded for us as captured by the large beam-trawl in the North Sea in February and March. These specimens would be a year old: in order to find younger and smaller specimens between June and Christmas a small-meshed trawl would have to be worked on the ordinary trawling grounds. The Marine Biological Association has not at present sufficient funds to give me the means of doing this. I have had to obtain my results by going out in deep-sea trawlers, living with the men, and taking whatever opportunities occurred in the course of the regular fishing operations. J. T. Cunningham.

Marine Biological Laboratory, Plymouth, Nov. 21.

Weights Proceeding by Powers of 3.

The following rule gives the allocation of weights of 1, 3, 9, &c., necessary for making up any given weight.

Find the least value of $\frac{1}{2}(3^n - 1)$ which exceeds, or is equal to, the given weight. Add it to the given weight, and express the sum in the ternary scale. The digits will indicate the weights to be used, and the pan in which they are to be put, according to the following scheme:—

Digit 2 indicates the positive pan,
,, 0 ,, ,, negative ,,
,, 1 ,, that the weight is not to be used.

Example.—Let 500 be the given weight to be made up. The number to be added is $\frac{1}{2}(2187 - 1) = 1093$, and the work is as follows:—

			Positive pan.	Negative pan.
500				
1093				
3)1593				
3)531	remainder	0	— ...	1
3)177	,,	0	— ...	3
3)59	,,	0	— ...	9
3)19	,,	2	27 ...	—
3)6	,,	1	— ...	—
3)2	,,	0	— ...	243
0	,,	2	729 ...	—

756 − 256 = 500.

I should be glad to learn whether this rule has been previously published. J. D. Everett.

5 Princess Gardens, Belfast, November 18.

Measures of Lunar Radiation.

In your issue of the 13th inst. (p. 44) you have, under the above heading, a notice of a paper in vol. xxiv. of the Proceedings of the American Academy of Arts and Sciences, by Mr. C. C. Hutchins.

The so-called "new thermograph" is obviously, with very slight differences in constructive details, the apparatus used here for some years past. We have employed the thermo-couple in place of the ordinary thermopile in our determinations of lunar radiant heat from the year 1870, and the condensing mirror of focal length about equal to its aperture from the commencement of our heat-work in 1869 (Proc. Roy. Soc., No. 112, 1869, and Nos. 122 and 123, 1870); and about four years ago we replaced the brittle bismuth and antimony alloys by the more tractable metals iron and German silver, for the same reasons which weighed with Mr. Hutchins.

We cannot give an unqualified assent to Mr. Hutchins's conclusions as to absorption of lunar radiant heat in our atmosphere, but I will defer remarks upon this for the present; I may say, however, now, that I have looked over Mr. Hutchins's paper, and he appears to have entirely overlooked Dr. Copeland's extensive and careful work here on the lunar phase curve and the law of absorption in our atmosphere (Phil. Trans., vol. clxiii. p. 587), or he would not have made the sweeping assertion that, "previous to the invention of the bolometer, no instrument existed capable of dealing accurately with so small an amount of heat as the moon affords," a statement which, from what I know of Prof. Langley, I feel confident he would not fully endorse, notwithstanding his success in working with that instrument.

In conclusion, may I congratulate Mr. Hutchins on having taken up with so much apparent manipulative skill and energy so interesting an investigation, and one in which the workers have been so few, and wish him every success? Rosse.

Birr Castle, Parsonstown, November 29.

The Distances of the Stars.

It is quite a familiar illustration to represent the distances of the stars in terms of the *light-year*, but I am not aware that it has been noticed that the same figures which express in years the time light occupies in reaching the earth from a star, will also express in miles the distance of the star upon a scale of the radius vector of the terrestrial orbit to the inch. The illustration appears to me useful, as it gives, perhaps, a more distinct idea of the isolation of the solar system in space than can be otherwise obtained, and does not introduce the question of time into the measurement of distance. Thus if the annual parallax of 61

Cygni is assumed to be 0"·434, which is probably very nearly correct, it will take 7½ (7·464) years for its light to reach the earth, and 7½ (7·499) miles will represent the distance of this star on a scale that gives 1 inch to the distance of the sun from the earth.

JOHN I. PLUMMER.

8 Constitution Hill, Ipswich.

Great Waterfalls.

I SHALL be much obliged to any of your readers who can inform me where I can find descriptions of the waterfalls named below:—

Falls of the Rio Grande near Guadalajara, Mexico, referred to by Miss Kingsley in "South by West."

Falls in the Ala-tau Mountains, Central Asia, stated in the "Universal Geography" as consisting of falls of 600, 350, and 350 feet separated by rapids.

Lattin, in Swedish Lapland, stated in the "Universal Geography" as of the height of 400 feet. It is also mentioned in the "Popular Cyclopædia," but I could hear nothing of any waterfall of that name when travelling in Lapland some few years since.

Aguara-y, in Paraguay, also classed amongst the great waterfalls of the world in the table in the "Universal Geography," as of the height of 409 feet.

Falls of the Pykara, India.

Falls of the Ooma Oya and Badulla Oya, Ceylon.

Any particulars of any of these falls will be most useful.

ARTHUR G. GUILLEMARD.

Eltham, Kent, November 22.

AID TO ASTRONOMICAL RESEARCH.

A CIRCULAR was issued last summer announcing the gift by Miss Bruce of 6000 dollars for aiding astronomical research. No restrictions were made upon its expenditure which seemed likely to limit its usefulness, and astronomers of all countries were invited to make application for portions of it, and suggestions as to the best method of using it. Eighty-four replies have been received, and with the advice of the donor the entire sum has been divided so as to aid the following undertakings:—

(3) Prof. W. W. Payne, Director of the Carleton College Observatory. Illustrations of the *Sidereal Messenger*.

(6) Prof. Simon Newcomb, Superintendent of the *American Nautical Almanac*. Discussion of contact observations of Venus during its transits in 1874 and 1882.

(16) Dr. J. Plassmann, Warendorf. For printing observations of meteors and variable stars.

(23) Prof. H. Bruns, Treasurer of the Astronomische Gesellschaft. To the Astronomische Gesellschaft for the preparation of tables according to Gyldén's method for computing the elements of the asteroids.

(27) Prof. J. J. Astrand, Director of the Observatory, Bergen, Norway. Tables for solving Kepler's problem.

(29) Prof. J. C. Adams, Director of the Cambridge Observatory, England. Spectroscope for the 25-inch telescope of the Cambridge Observatory.

(36) Prof. A. Hirsch, Secretary of the International Geodetic Association. To send an expedition to the Sandwich Islands to study the annual variation, if any, in latitude.

(40) Mr. H. H. Turner, Assistant in Greenwich Observatory. Preparing tables for computing star corrections.

(45) Prof. Edward S. Holden, Director of the Lick Observatory. Reduction of meridian observations of Struve stars.

(46) Prof. Lewis Swift, Director of the Warner Observatory. Photographic apparatus for 15-inch telescope.

(54) Prof. Norman Pogson, Director of Madras Observatory. Publication of old observations of variable stars, planets, and asteroids.

(57) Dr. Ludwig Struve, Astronomer at Dorpat Observatory. Reduction of observations of occultations during the lunar eclipse of January 28, 1888, collected by the Pulkowa Observatory.

(60) Dr. David Gill, Director of the Observatory of the Cape of Good Hope. 1. Reduction of heliometer observations of asteroids. 2. Apparatus for engraving star charts of the Southern *Durchmusterung*.

(78) Prof. A. Safarik, Prague. Photometer for measuring variable stars.

(79) Prof. Henry A. Rowland, Johns Hopkins University. Identification of metals in the solar spectrum.

Of the remaining replies many describe wants no less urgent than those named above. Some relate to meteorology or physics rather than to astronomy, some to work already completed, and others were received too late to be included. Two important cases may be specially mentioned. In each of them an appropriation of a part of the sum required would have been made; but in one, in our own country, an active and honoured friend of the science undertakes the whole; and in the other, in France, the generous M. Bischoffsheim, already known as the founder of the great Observatory at Nice, ignoring political boundaries and the comparative selfishness of patriotism, came forward and gave the entire sum required. The same sky overarches us all. It is to be hoped that the above-named, and other foreign institutions, will obtain more important aid from neighbours when these become aware how highly the work of their men of science is appreciated in this country. The replies not enumerated above are confidential, and cannot be mentioned except by the permission of the writers. But they have placed me in possession of important information regarding the present needs of astronomers. In several cases a skilful astronomer is attached to a college which has no money for astronomical investigation. He has planned for years a research in the hope that some day he may be able to carry it out. A few hundred dollars would enable him to do this, and he offers to give his own time, taken from his hours of rest, if only he can carry out his cherished plans.

Such valuable results could be attained by the expenditure of a few thousand dollars, that no opportunity should be missed to secure this end. Fortunately, the number of persons in the United States able and willing to give liberally to aid astronomy is very large. It is hoped that some of them may be inclined to consider the case here presented. The income derived from a gift of one hundred thousand dollars would provide every year for several cases like those named above. A few thousand dollars would provide immediately for the most important of the cases now requiring aid. The results of such a gift would be very far-reaching, and would be attained without delay. Correspondence is invited with those wishing to aid any department of astronomy, either in large or small sums, by direct gift or by bequest.

EDWARD C. PICKERING.

Harvard College Observatory,
Cambridge, Mass., U.S.A., November 11, 1890.

NOTE ON THE DISAPPEARANCE OF THE MOA.[1]

MAJOR MAIR, in an interesting paper on the disappearance of the Moa in vol. xxii. of the Transactions of the New Zealand Institute, makes, on p. 71, the statement that he is a "supporter of the belief

[1] Read before the Philosophical Institute of Canterbury, October 2, 1890, by H. O. Forbes, Director of the Canterbury Museum, Christchurch, New Zealand.

that the Maoris," from the absence of all mention of the bird from their songs and traditions, "never had any personal knowledge of the Moa." Major Mair so intimately knows the history and literature of the Maoris, and their habits and modes of thought, that one—especially one like myself who has had time as yet to acquire only a small amount of experience of New Zealand things—can scarcely hope to contribute any suggestion on the subject of the history of the Moa which has not occurred to this specialist.

Still, the following observations, made last year during a very complete exploration of a recently discovered cave in the property of Mr. Monck, near Sumner, lead me to think that the Maoris must have been personally acquainted with the *Dinornis*. The exploration was conducted under my own direction by two very trustworthy workmen, and the more important finds in it have been described in a paper read before the Institute last session by the President. The cave, it is certainly known, has been closed since before the advent of Europeans to Canterbury, but for how long before it is impossible to determine. The condition of the cave on entry gave all the appearance of having been untouched since the last dwellers in it left it. Its entrance was covered over by a very extensive landslip, which evidently fell during the absence of its frequenters, as no human bones were discovered in it. Quarrying occupations have been carried on amid the material of this landslip for between twenty and thirty years. These operations, on reaching last year the live rock of the hills, disclosed an aperture through which a lad squeezed himself into the cave. On its floor were found implements in wood and in greenstone, half-burned pieces of timber and fire-making apparatus, so lying as to give the doubtless correct impression that its occupiers intended to return. The greenstone objects were beautifully made, some of them; while the implements of wood, such as the canoe bailer, the paddle, and the fragment of a paddle handle, exhibit ornamentation characteristic of the Maoris. On the floor of the cave were found also numerous largish fragments of Moa bones, partly burned and partly broken, scattered round the last fireplace, or lying on the surface of the ground in the inner caves. In the kitchen-midden in front of the cave were found many fish-hooks and barbed spear tips, made of bone from the same birds. On the surface I picked up several bones of more than one individual of a species of swan, which I described to the Institute last year under the name of *Chenopis sumnerensis*. Just below the surface of an untouched part of the midden, I myself picked out pieces of Moa egg-shell, each with its shell membrane perfectly preserved. The question, therefore, stands thus: The Moa egg-shells, being among the refuse of the feasts of the occupants of the cave, who used the carved bailer, are the remains, it is legitimate to argue, of the eggs they used for food. There is no purpose I can think of for which pieces of shells of rotten eggs could be used; for eggs exposed on the ground, or buried under the soil, with their contents, would soon burst or disintegrate into fragments. It may be inferred, consequently, that these eggs were found in a more or less fresh condition, and were brought into the cave for food purposes. If they were sufficiently fresh for food, it is obvious that the birds that laid them could have been then still living, and probably were so; and that the bones from which the frequenters of this cave made their implements were as likely to be obtained directly from birds which they killed or might have killed. It may be suggested that eggs of Moas might have been found sufficiently whole to be used for utensils. The fragments that I found could not have been so used, as demonstrated by the condition of the membrane lining the interior. In the Sumner caves explored by Sir Julius von Haast, and at many Maori encampments, the remains of Moa eggs have been found abundantly in the kitchen-middens, and in such positions among the *débris* of their meals as to suggest that they had been used for food.

The black swan (*Chenopis atrata*), the only undomesticated swan in the country, was introduced into New Zealand from Australia a number of years after the settlement of Canterbury. The bones of the swans found in the Sumner cave were consequently also brought there by the feasters who ate the Moa eggs, and they, too, must have been, therefore, contemporaries of the Moa.

The figure of a dog carved out in wood was also discovered in the cave. It probably formed the termination of the handle of a paddle. A good figure of it may be found in the President's paper to which I have already referred. The Maori dog must, therefore, also have been contemporaneous with the Moa, and with the now, in New Zealand, non-indigenous (if not altogether extinct) swan *Chenopis sumnerensis*.

The fishing family, or families, who fed on the Moa eggs, and who last occupied the Sumner cave, were, as far as the style of their ornamentation and handiwork can decide for us, as much Maoris as those who carved the woodwork of the typical Maori dwellings of the King Country, or executed the ornamentation of which our museums exhibit specimens labelled "Maori"; and they were Maori in contradistinction to an earlier more primitive people who have been named "Moa-hunters," as is testified by their highly-executed and polished greenstone work.

How long ago it is since the Maori and the Moa were living together no evidence has yet been afforded by the Sumner cave explorations. A very great deal still remains to be done in the determination of the extensive osteological and other material obtained. It is being slowly examined; and when this work has been accomplished, some more light may possibly be thrown on the question of which this note forms the subject.

GLACIAL STRIÆ AND MORAINIC GRAVEL IN NORWEGIAN LAPLAND FAR OLDER THAN "THE ICE AGE."

AROUND the inner part of the Varanger Fjord, the mountains are low, and consist chiefly of sandstone and conglomerate, the strata of which lie in a nearly horizontal position. Between the village of Nesseby and the farm, Mortensnes, a mass of unstratified conglomerate or breccia occurs at least 50m. thick. Its component stones, which have been mostly derived from Archæan rocks (gneiss, &c.) are not properly water-worn pebbles, but have only their edges rounded, while flat faces may often be observed among them. A few of them consist of dolomite. On some of these fragments very distinct striæ occur, while similar markings may occasionally be detected on other kinds of material among the included stones. As in recent moraines, it would seem that here also the depth and distinctness of the engraving have had some relation to the relative hardness of the material. Not far from this conglomerate a smaller layer of a similar rock lies in the sandstone. The conglomerate is here very friable, and by its weathering a part of the upper surface of the hard sandstone under it has been laid bare. On this surface some excellent glacial furrows have been preserved. I had the pleasure of laying before a meeting of my geological colleagues on October 27 my specimens and diagrams. They all agreed with me in believing that in this deposit we have evidence of glacier-action dating back to the time of the sandstone and conglomerate of Lapland. The geological age of these strata is not yet settled, as no fossils have been found in them. Dr. Dahll has referred the formation to the Permian period. I think it not improbable that it belongs to the Cambrian or Silurian series, which in other parts of Scandinavia play so large a part in our mountain system.

Further details will be published in the year-book (*Aarbog*) of the Geological Survey of Norway for 1890.

Kristiania, November 29. HANS REUSCH.

NOTES.

THE anniversary meeting of the Royal Society was held on Monday at Burlington House. Sir G. Stokes resigned the presidency in favour of Sir William Thomson. The new Council was elected, and Sir G. Stokes presented the medals, a list of which we have already published. The official report of the proceedings is not yet ready. The annual dinner was held at the Hôtel Métropole in the evening, and, as usual, it was very numerously attended. Many of the speeches were so long that it is impossible to reproduce them here, but it is fitting that Dr. Hopkinson's reply for the medallists should be put on record. He said :—"You have done me great honour in asking me to respond to this toast, but the honour carries its burden with it. I could have wished for your sakes that the duty had been in hands abler for its performance. In matters of science, so far as nationality exists at all, it must be held to depend not upon the accidents of government, but upon community of descent and community of language. If you were to ask Prof. Newcomb, I have no doubt he would tell you that he was of the same nation as Bacon and Newton. We are undoubtedly of that nation, it therefore follows that Prof. Newcomb is our fellow-countryman. But intellectually Newcomb is a descendant of Newton in a peculiar sense. Newton not only originated that greatest of all scientific generalizations, the law of universal gravitation, but followed out in some measure its effects in the perturbation of the bodies of the solar system. Newcomb has attained to the proud position he now holds by advancing the theory of gravitation in its application to the details of the motion of the moon and some other of the planetary bodies. When Prof. Newcomb visited Birmingham some 16 years ago, he did me the honour of being my guest. He had then attained a high reputation. I little thought that on the day on which he should receive the highest honour the Royal Society has to bestow, I should myself receive a Royal Medal. Of Prof. Hertz and his work, I could say much of its connection with our own Maxwell, and of its immediate and enthusiastic appreciation in this country; but Prof. Hertz is here to-day, and can answer for himself far better than I could have answered for him. It is one of the boasts of modern science that she can accomplish by inanimate means many results which it was supposed that Nature had reserved for the laboratory of the living body. The work of Prof. Fischer belongs in part to this class; amongst other work he has produced by synthesis from inorganic sources many definite sugars, and in so doing has greatly extended the territory of chemistry into the domain of physiology. Rather than speak of Mr. Wallace's work, I would set him forth as an example of that chivalrous feeling which one would wish men of science should always exhibit. You all know the story of how Wallace had worked out the theory of natural selection and was ready to publish; of how he learnt that Darwin had worked it out further and worked at it earlier, and how he postponed his own publication till Darwin had time to take the first place. When we read of the noble work which is being done in France and in Germany by Pasteur and by Koch, and others, we feel with much bitterness that we do not live in a free country. The work which Dr. Ferrier has done on the brain proves that we have men here as capable of physiological discovery by experiment as anywhere abroad, and that, if there is fear that we may fall behind, it is because our investigators are unnecessarily hampered in their work. My own case in physics is very analogous to Dr. Ferrier's in physiology—we are both of us professional men, we both of us desire to further the pure science of our subjects on lines suggested by our professional work. I say deliberately that if I had been obliged to obtain the sanction of a Government Department to make experiments or to make them in a licensed place it is very little experimental work I could have done; I should not have been in the proud position of one of your medallists to-day. Neither physics nor physiology can be efficiently advanced by mere observation: the more powerful method of experiment is necessary. If we must have laws restraining our best men, let us at least admit what it costs us. Speaking for myself, looking back, I have been fortunate in my surroundings. My father cultivated in me a taste for science from a time before I can remember, my mother gave me the first systematic instruction of which I have any recollections. If my father gave me my first taste for science, you may be sure that taste was encouraged at Owens College. Mathematics is the most essential weapon of the physicist, and nowhere can mathematics be learned as at Cambridge. I owe to Sir William Thomson the first impulse to experimental work in electricity and magnetism. He has been to me for many years the kindest of friends, always ready to encourage and to help. Looking at the present, I admit that your Council, in awarding me a Royal Medal, have raised me not a little in my own estimation. There is one point of view from which this cannot be regretted, if a man's past work obtains for him honour from the highest and most competent tribunal: surely that should make him feel that it is incumbent upon him to endeavour to do more and better work of the same kind. This, gentlemen, speaking for the other medallists and for myself, is the best thanks we can return you—to endeavour to justify you in the future in giving us these honours to-day."

LETTERS have been received from Mr. J. Graham Kerr, Naturalist to the Pilcomayo Expedition, dated from the s.s. *Bolivia* on that river, in lat. 24° 58′ S., long. 58° 40′ W., on October 4 last. The vessel had got so far up the Pilcomayo with great difficulty, owing to the extreme shallowness of the water, and had stuck exactly in the same spot since June 14. They had almost given up all hope of ever getting out, when on October 4 a relief party of twenty soldiers reached them and brought assistance. Some of the soldiers and Captain Page's son (Captain Page himself having died on August 2, whilst proceeding to Corrientes for medical advice) came back immediately by land, while Mr. Graham Kerr and the remainder of the party proposed to return down stream in the *Bolivia*. If that turned out to be impossible, it had been determined to burn the boat, and return to the La Plata overland. The Pilcomayo Expedition must therefore be considered to be at an end.

THE Scientific Committee of the Royal Horticultural Society have undertaken, under the direction of Dr. D. H. Scott and Dr. Francis Oliver, to investigate the effects of London fogs on cultivated plants. The Royal Society has granted £100 in aid of the experiments.

MANY horticulturists feel that there should be some permanent memorial of the services rendered by the late Mr. Hibberd to horticulture. A meeting, therefore, will be held to take the matter into consideration.

THE authorities of the Natural History Museum have placed in the Central Hall of that institution a small temporary exhibit, consisting of a set of highly magnified daawings of Bacteria. It includes such prominent forms as *Bacillus tuberculosis*, Koch, and the *Bacillus* of fowl cholera, and is the work of Dr. W. Migula.

THE Board of Agriculture proposes the appointment of a widely representative body under whose direction all examinations in dairy work shall be held.

The Photographic Society has now secured premises which are likely to be suitable for its work. At the meeting of the Society on November 11, Mr. W. S. Bird gave all necessary information on the subject. The new quarters are "in a fine building of considerable architectural pretension," exactly opposite the centre of the British Museum. They consist of one large room, capable of holding about sixty persons; a smaller room, suitable for a library; a good dark-room; and a smaller one for a similar purpose.

The workshop accommodation of the Physical Laboratory in the University College of Wales, Aberystwith, has recently been considerably extended, and arrangements are being made for a course of instruction in electrical engineering. The recent additions include a Crossley D. high-speed electric lighting engine, Crompton dynamo (shunt and compound-wound), and a Crompton D.D. arc lamp, &c.

The following lectures on scientific subjects will be delivered at the Royal Institution before Easter:—Prof. Dewar, six Christmas lectures to juveniles, on frost and fire; Prof. Victor Horsley, nine lectures on the structure and functions of the nervous system (part i. the spinal cord, and ganglia); Prof. C. Meymott Tidy, three lectures on modern chemistry in relation to sanitation; the Right Hon. Lord Rayleigh, six lectures on the forces of cohesion. The Friday evening meetings will begin on January 23, when a discourse will be given by the Right Hon. Lord Rayleigh on some applications of photography; succeeding discourses will probably be given by Lord Justice Fry, Prof. J. W. Judd, Prof. A. Schuster, Dr. E. E. Klein, Mr. Percy Fitzgerald, Dr. J. A. Fleming, Dr. Felix Semon, Prof. W. E. Ayrton, and other gentlemen.

The second series of lectures given by the Sunday Lecture Society begins on Sunday afternoon, December 7, in St. George's Hall, Langham Place, at 4 p.m., when Sir James Crichton Browne, F.R.S., will lecture on "Brain Stress." Lectures will subsequently be given by Mr. Whitworth Wallis, Mr. Edmund Gosse, Mr. Eric S. Bruce, Dr. Henry Hoole, Sir R. S. Ball, and Prof. G. S. Boulger.

Early on Monday morning the inhabitants of the valley of the Ness, in Inverness-shire, were alarmed by another shock of earthquake. The *Times* says that a slight tremor was felt shortly before midnight, and this was followed about ten minutes past 12 o'clock by a sharp shock, accompanied by a low rumbling noise. People were awakened by the shaking of their houses, but the shock was of short duration, and was not so serious as that experienced a fortnight ago.

The United States National Electric Light Association will hold its thirteenth convention at Providence on February 17, 18, and 19, 1891. The following subjects will be dealt with:—How can the National Electric Light Association best serve central station interests? by C. R. Huntley; distribution of steam from a central station, by F. H. Prentiss; distribution and care of alternating currents, by T. Carpenter Smith; municipal control of electric railroads, by M. W. Mead; the Ferranti system, by C. B. Haskins. *Science* says that the committee has not only secured the promise of these papers, but has named a person to open the discussion on each paper—a plan which can hardly fail to increase the value and interest of the proceedings.

In his message to Congress, presented on Monday, President Harrison said Congress would be asked to provide means for the acceptance of the invitation of Italy to take part in a Conference to consider the adoption of a universal prime meridian. He further suggested the passing of a general law giving the Executive discretionary authority to accept foreign invitations to Conferences having for their objects international reforms in science, sanitation, &c.

There is much complaint among American men of science with respect to the effect of the McKinley Bill on the cost of scientific instruments. The tax on microscopes has been raised to 60 per cent., so that a microscope which can be bought in Germany for 94 dollars costs in the United States 150.40 dollars. "Not content," says the New York *Nation*, "with the attack on the microscope, McKinley increased the duty on mathematical glass instruments from 45 to 60 per cent. *ad valorem*. Everybody knows the importance of glass tubes in laboratory work; well, the brave McKinley increased the tax on them from 40 to 60 per cent. Everyone knows the value of telescopes in astronomy and navigation. McKinley has increased the duty on them from 45 to 60 per cent. His keen protective eye also fell on 'raddle,' a substance used in polishing lenses for microscopes and telescopes, so he put the duty on that at 1.50 dollars per ton. What rate per cent. this is we are unable at this moment to say, but nobody but an ignorant barbarian would have taxed it at all. Everyone knows the value of spy-glasses on shipboard. McKinley has raised the tax on them from 45 to 60 per cent., and to prevent cheap navigation he has raised the tax on compasses from 35 to 45 per cent. Glass disks for optical instruments he has also raised from 45 to 60 per cent. He has done the same thing by glass tubes for thermometers."

The Fishery Board for Scotland has issued a memorandum on the present state of the shore and sea fisheries of Scotland, by Dr. T. Weymss Fulton, secretary for scientific investigations. His review of the subject brings out the following facts:—(1) That the shore fisheries, especially those for lobsters, crabs, oysters, and mussels are steadily declining. (2) That the number of fishermen, the number of fishing-boats, and the value of the boats and gear, are decreasing. (3) That the number of Scottish beam-trawlers is increasing. (4) That the number of English beam-trawlers which have forsaken the less productive fishing-grounds off the English coast and have resorted to those lying off the Scotch coast is increasing year by year.

The Pilot Chart of the North Atlantic Ocean, issued by the Hydrographer of the United States, shows that the month of October was very stormy north of a line from Bermuda to the British Isles. The month opened with a severe storm about 500 miles north-east from Newfoundland, and pressures below 28·61 inches. There was also at this time a storm in the North Sea, which appears to have originated off Cape Sable on September 27. A marked feature of the month was the existence of a great anticyclone extending from the Azores to near the British Isles, which caused the storms originating to the west of it to take a north-east instead of an east-north-east direction. Considerable fog was reported off the Banks and west of the Irish Channel, but the amount for the month was probably not greater than the average. More ice than usual for the time of year was reported off the Banks as far south as the 45th parallel.

Symons's Monthly Meteorological Magazine for November contains a climatological table for the British Empire for 1889. These interesting results of a certain number of well distributed stations, prepared from the summaries published in the *Magazine* each month, have been continued for many years, and, as the author points out, the extremes are monopolized year after year by the same stations. The highest temperature in the shade was 109°·0 at Adelaide on January 13; for the last five years Adelaide has recorded the highest temperature in the shade, reaching 112°·4 in 1886. It had also the highest temperature in the sun, 170°·7, and was the driest station during the year, having a mean humidity of 63 per cent. The lowest shade temperature was recorded at Winnipeg, on February 23, – 42°·6; only once does any other station come within 20° of it. It had also the greatest range in the year, the greatest mean daily range, 24°·5, the lowest mean temperature, and the least rainfall, 14·95 inches. The highest mean temperature was 80°·5, at Bombay, and the greatest rainfall 73·79 inches, at Trinidad. London was the most cloudy and the dampest station, the mean humidity being 81 per cent. The brightest station was Malta, which had little more than half the cloud of London.

SPEAKING a few days ago at Agra College, the Viceroy of India expressed his approval of the proposal to add scientific and technical training to the curriculum at Indian Colleges, and hoped that it would tend to stimulate and resuscitate some of those arts and industries for which India was famous in by-gone days. If this is really the result, it will be a striking instance of the importance of scientific and technical instruction.

A NOVEL whaling expedition is about to be undertaken by three American whalers—*Hume*, *Grampus*, and *Nicoline*—which have gone to the Arctic regions to winter at the mouth of the Mackenzie River. In order to be well supplied with food, they have taken what will last for two years, and they expect also to get food from the whalers in the summer. This is the highest point any whaler has reached, being 1000 miles from the North Pole. Directly the ice breaks after the winter, the whales come to the mouth of the river in great numbers to feed, and it is expected that a large number of them will be secured. If the experiment proves successful, it will cause a revolution in the whaling industry, as vessels at present have to spend several months on the voyage to good whaling-ground, and then have only a very short time for hunting.

THE new number of the Journal of the Marine Biological Association of the United Kingdom (new series, vol. i., No. 4) opens with a list of governors, founders, and members. In addition to the report of the Council for the year 1889–90, and the director's report, it contains the following papers:—Notes on recent experiments relating to the growth and rearing of food-fish at the Laboratory; report on the surface collections made by Mr. W. T. Grenfell in the North Sea and West of Scotland, by G. C. Bourne (with plate); notes on the herring, long-line, and pilchard fisheries of Plymouth during the winter 1889–90, by W. Roach; notes on the hydroids of Plymouth, by G. C. Bourne (with plate); a complete list of the Opisthobranchiate Mollusca found at Plymouth, by W. Garstang (with plates); notes and memoranda—(1) colour-changes in *Cottus bubalis*, by J. T. Cunningham, (2) note on the British Palæmonetes (*P. varians*), by W. F. R. Weldon, F.R.S.

HAZELL'S Annual for 1891 has been published. This is the sixth year of issue, and we need scarcely say that the volume contains a vast mass of useful information, clearly arranged. In the additions included in the present issue the editor has been careful to keep the work well up to date.

To the new number of the Natural History Transactions of Northumberland, Durham, and Newcastle-upon-Tyne (vol. x., Part 2), Mr. R. Howse contributes a note on the South Durham salt borings, with remarks on the fossils found in the magnesian limestone cores, and the geological position of the salt; a catalogue of the local fossils in the Museum of the Natural History Society; and a catalogue of the fishes of the rivers and coast of Northumberland and Durham and the adjacent sea. The number also contains the report of the Committee for 1888–89.

THE Geological Survey of New Zealand has issued its reports of exploration during 1888–89, with maps and sections. The Director, Sir James Hector, notes that the Department was very fully represented at the Melbourne Exhibition by collections and maps illustrating the geological structure and mineral wealth of the colony. He also mentions that, as a contribution to the work of the Australasian Association for the Advancement of Science, a complete census of the mineral species which have been found in New Zealand has been compiled, together with the localities where found, the names of the first discoverers, and the dates. From this census it appears that 237 species are now recorded.

MESSRS. DULAU AND CO. have published a catalogue of the botanical works which they offer for sale. It includes a large number of valuable books relating to Phanerogamia.

IN 1865, Mr. J. G. Lockhart, while serving as an officer of the Hudson Bay Company, wrote some interesting notes on the moose in the far north of British America. These notes have been preserved in the archives of the Smithsonian Institution, and now appear in the Proceedings of the National Museum. Referring to the hunting of the moose, Mr. Lockhart says the most usual way is to approach the animals on snow-shoes or on foot, as only a hunter knows how, and shoot them. The old men who are not able to walk much in deep snow make a kind of fence of three poles tied equidistant from each other, a little taller than a man, stretching, perhaps, for two days' march between lakes, or a lake and a river, or between two mountains, or in any particular place where the moose are accustomed to pass. Spaces are left vacant here and there in this fence, and in these snares are set. In autumn, during the rutting season, the hunter carries with him the clean, dried shoulder-blade of a moose, and when he hears the call of the male moose, which is audible at a distance of several miles, he rubs the shoulder-blade against a small, dry tree and imitates the call of the male. The moose, as soon as he hears the sound, imagines, no doubt, that it is another moose, and runs in the direction, till met by a shot. The male is very dangerous at that season, especially when wounded. Many years ago, before guns and ammunition found their way into the country, the Indians used to build snow embankments near favourite feeding places, and lie hid there for days until a moose should chance to pass near, when they would kill him with arrows.

THE U.S. Department of Agriculture has issued the third of a series of papers entitled "Contributions from the U.S. National Herbarium." It consists of a list of plants collected by Dr. Edward Palmer in 1890, in Lower California and Western Mexico. Great interest was felt in Dr. Palmer's trip to La Paz and vicinity, and his collection is said to have added much to what was previously known regarding the flora of that region.

AN interesting paper is communicated by Prof. von Hofmann to the current number of the *Berichte* upon the dissociation of carbon dioxide gas into carbon monoxide and oxygen by means of the electric spark. Dalton and Henry long ago showed that carbon dioxide, although formed by exploding a mixture of two volumes of carbon monoxide with one volume of oxygen by the passage of an electric spark, is again partially decomposed into carbon monoxide and oxygen by the continued passage of the spark. This dissociation, however, is very slow, and usually incomplete. Hofmann and Buff, in the course of their well-known work upon gaseous reactions, further showed that "the electric spark passes through carbon dioxide with a violet glow, producing at first a rapid increase in the volume, which, however, becomes less and less marked until at the expiration of about half an hour the separated carbon monoxide and oxygen recombine with a sudden explosion, the re-formed carbon dioxide at once commencing to be again dissociated." Deville and Berthelot afterwards investigated the same phenomena, and also found that the reaction was never complete, proceeding only until about 28 or 29 per cent. of the carbon dioxide was decomposed, but they never observed any explosive recombination as described by Hofmann and Buff. Prof. Hofmann has therefore determined the exact conditions under which the explosive recombination occurs. It certainly appears somewhat remarkable that the same spark can effect both dissociation and recombination, yet such, within the limits described in the memoir, is an actual fact. The first essential point to be observed is the length of path of the spark; the most suitable distance apart of the platinum terminals appears to be between two and a half and three millimetres, and Prof. Hofmann advises the use of adjustable terminals rather than the ordinary platinum wires fused into the side of the eudiometer. A Leyden jar in the circuit renders the occurrence of periodical explosions more certain. The spark should also pass at about a quarter the height of the gas column instead of, as usual, near the top. The current itself, moreover, should not be too strong; that from two Bunsen cells and only a moderate sized Ruhmkorff coil is quite sufficient, and yields the best results. It is also preferable to use a volume of carbon dioxide, previously dried over oil of vitriol, not exceeding ten cubic centimetres at a pressure of 650–700 mm.; eight c.c. give excellent results. Under these conditions the first explosion usually occurs in 15–20 minutes, and sometimes earlier. The flame commences in the neighbourhood of the spark, and then perceptibly spreads through the whole length of the gas column. It is coloured blue in the first explosion, and green in the succeeding ones owing to the volatilization of a little mercury vapour. The second and succeeding explosions occur after shorter intervals than the first. This experiment is certainly one of the most interesting in all the range of dissociation phenomena, and full details, with drawings of the apparatus, are given by Prof. Hofmann in his memoir.

The additions to the Zoological Society's Gardens during the past week include an Ocelot (*Felis pardalis*) from South America, presented by Mr. J. H. Bennett; a Common Fox (*Canis vulpes* ♀) from North Wales, presented by Mr. B. Myddelton Biddulph; two Cape Zorillas (*Ictonyx zorilla* ♀ ♀) from South Africa, presented by Mr. R. Southey; two Ring-necked Parakeets (*Palæornis torquatus*) from India, presented by Miss S. L. Hands; ten Thunder-fish (*Misgurnus fossilis*) from the Baltic Sea, five Golden Orfe (*Leuciscus orfus*), European fresh waters, purchased.

OUR ASTRONOMICAL COLUMN.

The Variations in Latitude.—The most important question discussed at the International Conference on Degree Measurement held at Freiburg on September 15 was that of the variability of terrestrial latitudes. The Central Bureau, represented by Drs. Helmert and Albrecht, communicated two notes, one by Dr. Albrecht, "Resultate der Beobachtungsreihen betreffend die Veränderlichkeit der Polhöhen," the other by Dr. Marcuse, "Resultate der fortgesetzten Berliner Beobachtungsreihen betreffend die Veränderlichkeit der Polhöhen." These papers, and a general account of the whole question of variation in latitude, first raised by Prof. Fergola at the Conference of Rome (1883), is given by M. Tisserand in the *Bulletin Astronomique* for September. The method adopted in the observations made at the different stations is that of Horrebow. It consists in forming nine groups, each containing eight or nine couples of stars, two groups at least being observed each evening. The two stars of each couple were of almost equal magnitude; their difference in right ascension was comprised between 3m. + 15m., and that of their meridian zenith distances between ± 12′, whilst the meridians were never separated more than 27°. By choosing such stars, and taking the arithmetical mean of the differences of zenith distances of the two components, the small error due to an imperfect knowledge of the movement of the micrometer wire is eliminated. At each station a number of couples of stars ranging from 1400 to 1700 have been observed during the whole of 1889 and the first three months of 1890. It is evident that if the same couple of stars could be observed throughout the year, during the day as well as the night, the variations in latitude could be obtained independently of the errors of the absolute declinations of the two stars, provided that we knew exactly the variations of these declinations during the whole interval of observation. These variations depend on the motion of the terrestrial axis (precession and nutation), on aberration, annual parallax, and proper motion. It is impossible to work in this way for two reasons, (1) stars cannot be observed in the day-time by means of the instruments employed; (2) only a very small number of observations could be made. The groups of stars referred to above have been formed in order to avoid these inconveniences, for the differences, from the mean declinations, of each of the couples may be used as if only a single couple had been observed. When the necessary corrections are applied to the calculations it is found that the latitudes of Berlin, Potsdam, and Prague, indicate clearly a diminution of about 0″·5 from August 1889 to February 1890. The observations made at Berlin from April 15 to August 30 in this year show an increase of 0″·4 in the latitude of this place during the interval considered, and point to a period of about a year. The fact that the latitude of a place is subject to an annual periodic variation is not entirely new, for Gaillot discussed 1077 observations of latitude made between 1856 and 1861. On arranging the observations according to the month in which they were made, the following differences from the mean value were obtained (*Annales de l'Observatoire de Paris*, p. 319):—

	Paris.	Potsdam.		Paris.	Potsdam.
	″	″		″	″
January	−0·23	−0·11	July	+0·25	+0·19
February	−0·06	−0·07	August	+0·16	+0·17
March	−0·03	−0·04	September	+0·13	+0·10
April	−0·03	0·00	October	−0·07	−0·03
May	+0·10	+0·05	November	−0·11	−0·14
June	+0·16	+0·14	December	−0·27	−0·26

These observations, therefore, indicate a difference of almost half a second between the observed latitudes in January and July. M. Nobile has discussed, from the same point of view, the observations made at Greenwich, Milan, Oxford, Pulkova, and Washington (*Bulletin Astronomique*, vol. v. p. 544). The Greenwich observations show a maximum of latitude in July and August, and a minimum in December and January, the amplitude of the variation being nearly 1″. At Washington a minimum also occurs at the end of the year, but at Milan it occurs in May. The Oxford observations show a maximum in the autumn, whilst those made at Pulkova do not appear to present any periodic variation with the seasons. But although these results are somewhat contradictory, those communicated at Freiburg clearly demonstrate the existence of a variation of 0″·5. It remains to be seen how the amplitude and the phase of the variation is affected by passing from the northern to the southern hemisphere, or when observations are made at two stations having appreciably the same latitude, but widely separated in longitude.

The cause of the variation has yet to be found. M. Tisserand has shown ("Traité de Mécanique céleste," vol. ii. p. 489) that the transportation of a mass of water, 0·10m. thick, from latitude + 45° to − 45°, and covering a tenth of the earth's surface, may cause the principal axis to move 0″·16. The weight of a column of water 0·10m. thick, is equal to that of a column of mercury 0·007m. thick, hence considerable changes in the barometric pressure may have an appreciable effect on the direction of the earth's axis. That the variations are connected with the succession of the seasons is manifest. This seems to indicate that temperature plays an important part, and that the variation is a result of the varying amount of heat received throughout the year by the atmosphere and the instruments. The theories of refraction require the atmosphere to have a regular constitution and a statical condition that is probably never realized. If the constitution varies with the season, the refractional effect must also change, and this may cause the difference in the observations of latitude.

Another probable cause was suggested by M. D. Lamey at the meeting of the Paris Academy on November 17. He showed that if the atmospheric tidal effects be calculated for each month in the year, the values obtained followed a curve very similar to that derived from the observed differences in latitude. That the sun and moon produce atmospheric tides must be incontestable. The physical consequence is that refraction phenomena must also vary with the tidal effect, and therefore the positions of stars may experience an annual periodic fluctuation comparable with that observed. The cause wherein lies the solution of the problem can only be definitely determined, however, after a more extended study than has yet been made.

NEW ASTEROIDS.—M. Charlois discovered the asteroid (298) on September 9. On October 3, what was supposed to be the same body was again observed by Charlois. Dr. Palisa also observed an asteroid near the computed position of (298) on October 11. It has since been found that the observations of October 3 and 11 must refer to another asteroid, and, as Dr. Palisa discovered (299) on October 11, the one thought to be identical with (298) will be reckoned as (300). M. Charlois rediscovered (298) on November 14. Dr. Palisa added (301) the list on November 16 (*Astronomische Nachrichten*, 3006).

The large number of asteroids now known renders it impossible for the Berlin Computing Bureau to furnish all the data for their observation. The editors of the *Berliner Jahrbuch* have therefore decided only to furnish predictions for the following asteroids:—

(1) Those that approach near the earth, and are therefore well adapted to the determinations of parallax.

(2) Those whose near approach to Jupiter renders them useful for determining his mass.

(3) Those remarkable for a period having a closely commensurable ratio to that of Jupiter; such orbits being of the highest importance in the theory of absolute perturbations.

(4) Those that are of value for photometric work on account of their considerable brightness.

ZONA'S COMET (*e* 1890).—Dr. Bidschof gives the following elements and ephemeris of this comet in *Astronomische Nachrichten*, 3006:—

T = 1890 July 25·051 Berlin mean time.

$$\left.\begin{array}{l}\omega = 321^\circ\ 58' \\ \Omega = 84\ 45 \\ \iota = 153\ 28\end{array}\right\}\ \text{Mean Eq. 1890.}$$

Perihelion distance = 1·8996 (earth's mean distance = 1).

Ephemeris for Berlin Midnight.

1890.	R.A. h. m.	Decl. ° ′	Distance in terms of the earth's mean distance.
December 4	3 47·0	+ 34 50	1·53
„ 8	3 26·8	+ 34 19	1·59
„ 12	3 8·7	+ 33 36	1·65

The comet is, therefore, in the constellation Perseus, which is in the south about 10 p.m. It passed perihelion about the end of July, and is increasing its distance from the earth. M. Bigourdan, of Paris Observatory, describes the comet as "très faible (grandeur 12·5–13), et se présentait sous l'aspect d'une petite tache blanche, ronde, de 1′ environ de diamètre, avec condensation central assez diffuse et d'aspect un peu grande."

THE SCIENTIFIC WORK OF JOULE.[1]

PROF. DEWAR commenced by remarking that the Royal Institution had been so closely identified with the great workers in physical science that it was impossible to allow the work of Joule, whose researches had produced as marked a revolution in physical science as Darwin's in biology, to pass without recognition in the present series of Friday evening discourses. Sir William Thomson, as Joule's friend and fellow-worker to the last, had been invited to undertake the duty, and had agreed to do so; but at the last moment had been compelled to decline by reason of important official duties in Scotland, and the task had consequently devolved upon him.

Having given a brief account of Joule's parentage, early life, and education, Prof. Dewar reviewed, as fully as time would permit, his scientific work, which extended over about forty years, and was represented by 115 original memoirs. The first period (1838–43) was distinguished as that in which Joule educated himself in experimental methods, chiefly in connection with electricity and electro-magnetic engines. This work led him in 1840 to his first great discovery, the true law governing the relation between electric energy and thermal evolution, which enabled him later on to account for the whole distribution of the current, not only in the battery in which it is produced, but in conductors exterior to it. Joule was thus led to take up the study of electrolysis. Faraday had already made the discovery that electrolytic bodies could be split up into equivalent proportions by the passage of the same electric current; Joule saw that there would be great difficulty in finding out the distribution of the current energy, and accounting for the whole of it. After a laborious research he succeeded in showing that during electrolytic action there was an absorption of heat equivalent to the heat evolved during the original combination of the constituents of the compound body. The prosecution of his electrical researches rapidly brought Joule on the road to his great discovery of the mechanical equivalent of heat, it being clear from a footnote to a paper dated February 18, 1843, that he already had well in hand the study of the strict relations between chemical, electrical, and mechanical effects.

In working out these laws, it was to be remarked that Joule—in common with most inventors and seekers after new scientific truths—chose perhaps the most difficult means that could have been selected; and in looking back at his work in the light of present knowledge, it seemed simply astounding that he should have succeeded so completely as he did. The original coil used by Joule for the mechanical determination of heat (kindly lent for the occasion by Prof. Rücker) was shown, and the course of the experiment explained. The vast difficulties which Joule had to overcome in order to prove that there was a definite, permanent, and persistent relation between the amount of mechanical energy expended and the heat produced were commented on; the thermal effects being produced not directly but through the medium of an electric current varying in intensity, and calculations having to be made not only for these fluctuations, but for the effects of radiation, the movement of the air, and other indirect complications. The very small increment of heat to be measured obliged Joule to use thermometers of great delicacy, and these he had to devise and construct himself. One of the thermometers so used was exhibited.

Working in this way, Joule was able, by the end of July 1843, to state definitely that the amount of heat capable of increasing the temperature of a pound of water by 1° F. was equal to, and might be converted into, a mechanical force capable of raising 838 lbs. to the height of 1 foot. Soon afterwards he attained almost identical results by a more direct method—the friction of water passing through small tubes—which gave him 770 foot-pounds per unit of heat.

It was impossible, said the lecturer, to thoroughly appreciate Joule's work without glancing at the early history of the subject; and when one did so it was amazing to find how near men of the stamp of Rumford, Davy, and Young had been to Joule's great discovery, and yet missed it. Count Rumford was the first to clearly define the relation between the constant production of heat and loss of movement by frictional motion. He proved that the amount of heat produced by friction was continuous, and apparently unlimited; but he did not think of measuring the relation between the mechanical energy expended and the amount of heat produced. Alluding to the results obtained from this apparatus, the lecturer said that Count Rumford might have shown that in his experiments the heat produced was proportional to the time of working, and so obtained a result capable of being expressed in horse-power. The value so deduced from Rumford's experiments is not far removed from Joule's first number.

The experiments commenced by Count Rumford were carried on by Davy, at that time working with Beddoes at Bristol; and led to one of the most remarkable essays on heat of that period, which disposed for ever of the theory of the separate existence of caloric. Taking two pieces of ice on a cold day, Davy mounted them so that they could be rotated against each other with frictional pressure, the effect being that the pieces of ice were melted, the water so produced having a much higher specific heat than the original ice. To guard against the possibility of heat being conveyed to the frictional apparatus by the surrounding air, Davy made an experiment *in vacuo*, isolating the apparatus by means of ice; and found that under such conditions sufficient heat could be produced to melt wax placed in the receiver. The lecturer here showed an experiment illustrating the production of water by the friction of two pieces of ice *in vacuo*, under conditions of temperature much much severe than those of Davy's experiment.

Following Davy, Young devoted a great deal of attention to the subject, and by 1812 he and Davy had quite changed their opinions, and had adopted the view that heat and motion were convertible effects.

Having by July 1843 assured himself of the principle of his discovery, Joule now devoted his attention to the elaboration of methods of working, modifying, and repeating experiments in

[1] Abstract of the Friday evening discourse delivered at the Royal Institution of Great Britain on January 24, 1890, by Prof. Dewar, F.R.S.

various ways, but always approaching nearer and nearer to exactness, as shown by the following table of results :—

Joule's Values of the Mechanical Equivalent of Heat.

		Kilogramme metres.
Magneto-electric currents	1843	460
Friction of water in tubes	,,	424·6
Diminution of heat produced in a battery current when the current produces work	,,	499
Compression of air	1845	443·8
Expansion of air	,,	437·8
Friction of water	,,	488·3
,, ,, ,,	1847	428·9
,, ,, ,,	1850	423·9
,, ,, mercury	,,	424·7
,, ,, iron	,,	425·2
Heat developed in Daniell's cell	,,	419·5
,, ,, in wire of known absolute resistance	1867	429·5
Friction of water in calorimeter	1878	423·9

Prof. Dewar here exhibited and explained the action of the original calorimeter used by Joule. It was seen to consist of a set of vanes which were made to revolve in water by the falling of known weights through a definite and known height, the heat produced being due (after making the necessary deduction for the friction due to the momentum of the weights) entirely to the friction of the fluid. It was found that, whatever fluid was employed, the same definite results were obtained—a production of heat in the liquid bearing a constant relation to the unit of mechanical energy expended. The extreme delicacy of Joule's apparatus, and the marvellous accuracy of his observations, were shown by the fact that working with weights of 29 pounds each, and repeating each observation 20 times, the total increase of temperature did not exceed half a degree Fahrenheit. In contrast to this the lecturer showed, by means of apparatus kindly lent by Prof. Ayrton, the method now employed for repeating Joule's work and arriving at substantially the same results by much simpler means.

While continuing to work intermittently at his great discovery, Joule employed himself in the following years in elaborate investigations bearing upon the point of maximum density of water, specific gravity, and atomic volumes. An illustration of his method of determining maximum density was given by means of two large cylinders filled with water and connected by a narrow channel in which was placed a floating indicator. It was shown that the slightest variation in density of the water of either cylinder—variations far beyond the scope of the most delicate thermometer—set up currents which were immediately detected by the movement of the indicator, and that by this means it was quite possible to ascertain the exact temperature at which water attained its maximum density.

Joule's determinations of atomic volumes were marvellous at the time they were made, and were still interesting. Illustrations of his work in this direction were given by means of a solution of sugar, which was seen to occupy practically the same space as was occupied by an amount of water exactly equivalent to that combined in the carbohydrate, the carbon hypothetically combined with the water to form the sugar appearing to make no sensible difference to the volume; and in contrast to this was seen the enormous difference in volume brought about by dissolving two equal portions of soda carbonate, one portion being ordinary hydrated crystals, and the other portion being anhydrous, in equal volumes of water.

Joule's last great research was carried out conjointly with Sir William Thomson, and occupied nearly ten years of laborious inquiry. Its chief object was to prove that in compressing a gas the amount of heat produced is equivalent to the work done, and independent of the mere fact of the approach of the particles. But Joule was desirous of amplifying the inquiry, and in fact the work might be divided into three sections: (1) the study of gases passing through narrow apertures; (2) the velocity attained by bodies passing through the air; and (3) the temperature ultimately attained by such moving bodies. With respect to (2) and (3), it was shown that a body rotating in the air at the rate of about 150 to 180 feet per second increased in temperature by nearly 1° F., and that this increase of temperature was definite for a given velocity, and independent of the size of the moving mass and the density of the gaseous medium. With regard to (1), the relation of gaseous pressure and volume to temperature, the researches of Regnault had already shown that the simple law of Marriotte and Boyle could not stand by itself; and Joule sought to modify it by the study of gases passing through very small tubes or porous bodies. The investigations were carried out at Manchester on a large scale, and were assisted by a Government grant. Steam engines were employed to maintain a current of gas at a constant temperature and pressure through long coils of pipe placed in water tanks. They proved that any difference of temperature in the gas brought about in its passage through the porous body must be due to work done by it, and that this difference of temperature varied for different gases, according to their constitution. Working under the same conditions, hydrogen was shown to be reduced a small amount in temperature, air somewhat more (about 0°·3), and carbonic acid a much greater amount. A repetition of Joule and Thomson's experiment was shown by means of a 100-feet coil of lead pipe, compressed hydrogen, air, and carbonic acid gas being employed, and the original results verified in each case. The effect of this research was to enable Joule and Thomson to formulate a great improvement on the gaseous laws; for, instead of the product of the volume and pressure being strictly proportional to the absolute temperature, as it had been hitherto believed, they found that a new term was involved, which is equivalent to a constant divided by the absolute temperature and multiplied by the volume.

In conclusion, Prof. Dewar read the following letter, which he had received from Sir Lyon Playfair in response to his request for some reminiscences of Joule :—

January 20, 1890.

DEAR DEWAR,—You ask for some of my memories of Joule from 1842 to 1845, when I was Professor of Chemistry at the Royal Institution in Manchester. The great Dalton died in the autumn of 1844, and had long been President of the Manchester Philosophical Society. He naturally gave impulse to the study of science in that town, where there was an active band of young workers in research.

Joule was, even then, foremost among these; and the names of Binney, Williamson, Schunck, Angus Smith, Young, and others show that the spirit of scientific inquiry was active. We were also stimulated by the fact that Baron Liebig and Bunsen came to pay me visits during that time; they were men to excite research.

Joule was a man of singular simplicity and earnestness. We used to meet at each other's houses at supper, to help the progress of our work by discussion. Joule was an earnest worker, and was then engaged on his experiments on the mechanical equivalent of heat. He took me to his small laboratory to show me his experiments, and I, of course, quickly recognized that my young friend the brewer was a great philosopher. We jointly worked upon questions of far less importance than his great central discovery, but he was equally interested. I was very anxious that he should devote his life to science, and persuaded him to become candidate for the Professorship of Natural Philosophy at St. Andrews. He was on the point of securing this, but his slight personal deformity was an objection in the eyes of one of the electors; and St. Andrews lost the glory of having one of the greatest discoverers of our age.

When Joule first sent an account of his experiments to the Royal Society, the paper was referred, among others, to Sir Charles Wheatstone, who was my intimate personal friend. Wheatstone was an eminently fair man and a good judge, but the discovery did not then recommend itself to his mind. For a whole Sunday afternoon we walked on Barnes Common, discussing the experiments and their consequences, if true, to science. But all my arguments were insufficient to convince my friend; and I fear that then the Royal Society did not appreciate and publish the researches. I write from memory only, for I know that, later, no Society or institution honoured Joule more than the Royal Society and its members.

Not for one moment, however, did Joule hesitate in the accuracy of his experiments or his conclusions. He once suggested to me that we might take a trip together to the Falls of Niagara, not to look at its beauties, but to ascertain the difference of temperature of the water at the top and bottom of the fall. Of course the change of motion into heat was a necessary consequence of his views.

No more pleasant memory of my life remains than the fact that, side by side, at my lectures in the Royal Institution, used to sit the illustrious Dalton, with his beautiful face, so like that of Newton, and the keenly intelligent Joule. I can give no other explanation than the fact of organic chemistry being then a new science that two philosophers of such eminence should come to the lectures of a mere tyro in science. I used to look upon them as two types of the highest progress in science. Newton had introduced law, order, and number into the movements of masses of matter in the universe; Dalton introduced the same into the minute masses which we call atoms; and Joule, with a keen insight into the operations and correlation of forces, connected them together, and showed their mutual equivalence.

I do not know whether these memories are of any use to you, but, such as they are, they are at your disposal for your lecture on the friend of my youth. Yours sincerely,

LYON PLAYFAIR.

WEIGHING BY A SERIES OF WEIGHTS.

THIS subject, now under discussion in NATURE, is by no means new. The following remarks on the general theory of such questions may prove interesting. The problems are divisible into two classes:—

(1) To assign a series of weights so as to be able to weigh any weight of an integral number of pounds from 1 to n inclusive, the weights being placed in only one scale-pan.

(2) The same problem when the weights may be placed in both scale-pans.

Two other conditions may be imposed, viz.:—

(*a*) That no other weighings are to be possible.

(*b*) That each weighing is to be possible in only one way, *i.e.* to be unique.

The question considered in NATURE is of the second class, and is further subject to the two conditions above stated. Moreover, the problem for the number of pounds 1, 4, 13, 40, &c...., as solved by the series of weights 1; 1, 3; 1, 3, 9; 1, 3, 9, 27; &c...., respectively gives in each case the series containing the least number of weights for which the solution is possible.

For a number of pounds equal to 40, the solution may be given by means of a single algebraic formula, constituting an identity, viz.

$$(x^{-1} + 1 + x)(x^{-3} + 1 + x^3)(x^{-9} + 1 + x^9)(x^{-27} + 1 + x^{27})$$
$$= x^{-40} + x^{-39} + \ldots\ldots + x^{-1} + 1 + x + \ldots\ldots + x^{39} + x^{40}.$$

This is easily verified. When the left-hand side is multiplied out, the resulting powers of x are obtained by addition of certain indices, some positive and some negative. The indices in question are 1, 3, 9, 27, and, from the form of the factors, may in any single term be taken *either* positively or negatively. Thus one term on the left is $x^{-3} \cdot x^9 \cdot x^{27} = x^{-3+9+27}$, giving the term x^{33} on the right-hand side. The identity shows that every number from 1 to 40 inclusive can be thus composed by the numbers 1, 3, 9, 27, taken positively or negatively. It shows, moreover, since the coefficients of the several powers on the right are each unity, that the composition is unique. The identity includes also negative integers from -1 to -40. This is necessitated by the very nature of the question.

The above is one out of eight distinct solutions of the problem before enunciated. Before giving the other seven, it will be as well to show the principles of solution in general.

Consider, first, the problem of the first class in which weights can only be placed in one scale-pan. The number of pounds to be weighed being n, we must discover the ways in which it is possible to break up the expression

$$1 + x + x^2 + x^3 + \ldots\ldots + x^n$$

into similar expressions, for, as will be evident, each such factorization corresponds to a definite solution of the problem. By similar expression is to be understood one in which the coefficients are unity and the indices are in arithmetical progression.

At the outset may be remarked the trivial solution consisting of n ones corresponding to the unfactorized expression. There is one solution of this kind in respect of every number n.

Putting the expression in the form

$$\frac{1 - x^{n+1}}{1 - x},$$

it will be clear that if $n + 1$ be a prime number, the expression cannot be factorized in the required form. This is a consequence of the properties of prime roots of unity.

Hence, when $n + 1$ is prime, the only solution is obtained by taking n one-pound weights.

If, however, $n + 1$ be not prime, the number of solutions depends upon the composite character of $n + 1$. If $n + 1 = st$ where s and t are primes, we may write

$$\frac{1 - x^{n+1}}{1 - x} = \frac{1 - x^{st}}{1 - x} = \frac{1 - x^s}{1 - x} \cdot \frac{1 - x^{st}}{1 - x}$$
$$= (1 + x + x^2 + \ldots + x^{s-1})(1 + x^s + x^{2s} + \ldots + x^{st-s}),$$

a factorization of the required form.

Multiplying x^p in the first factor into x^{qs} in the second, we find that the number $p + qs$ is composed by p numbers equal to 1, and q numbers equal to s. In general, every number from 1 to n inclusive can be composed by means of $s - 1$ ones, and $t - 1$ s's. That is to say, that all numbers of pounds from 1 to n (where n is of the form $st - 1$) can be weighed, and in a unique manner, by means of $s - 1$ weights of 1 pound each, and $t - 1$ weights of s pounds each.

Another solution is obtained from the identity

$$\frac{1 - x^{n+1}}{1 - x} = \frac{1 - x^{st}}{1 - x} = \frac{1 - x^t}{1 - x} \cdot \frac{1 - x^{st}}{1 - x_t}$$

obtained from the former by interchange of s and t. These two solutions, together with the trivial one, constitute the complete set of three solutions. For brevity, these may be represented in the form—

$$1^{st-1},$$
$$1^{s-1}\, s^{t-1},$$
$$1^{t-1}\, t^{s-1},$$

where s^{t-1} means $t - 1$ s's, and so on.

From the above simple example it will be sufficiently clear that the number of solutions in the case of a given number n is entirely dependent upon the form of $n + 1$, when regarded as a product of prime factors. The number of solutions is not in all cases easy to determine, but some of the simpler results are interesting. Suppose the number $n + 1$ to be a product of k unrepeated prime numbers, and, under these circumstances, represent the number of solutions in regard to the number n by

$$[1^k].$$

Then it is easy to prove the relation—

$$[1^k] = 1 + k[1^1] + \frac{k(k-1)}{2!}[1^2] + \frac{k(k-1)(k-2)}{3!}[1^3] + \ldots$$
to k terms,

and thence to calculate the values of $[1^1]$, $[1^2]$, $[1^3]$,... in succession. The series of numbers thus obtained commences 1, 3, 13, 75, 541,... where it will be noticed that the second number, 3, corresponds with the result obtained above for the case of $n + 1$, being of the form st, or the product of two unrepeated primes. It may be observed that this series of numbers is of great interest, and presents itself frequently in mathematics, notably in Prof. Cayley's "Theory of the Analytical Forms called Trees" (see vol. xiii. and subsequent volumes of the *Philosophical Magazine*, and "Collected Papers," No. 203).

A much simpler case to consider is that for which $n + 1$ is merely a power of a prime number. If $n + 1$ be the kth power of a prime, represent the number of solutions in regard to the number n by

$$[k].$$

A small amount of reflection shows the truth of the relation

$$[k] = 2[k - 1];$$

whence

$$[k] = 2^{k-1}.$$

Turning now to the second class of problems, in which it is permissible to place weights in either or both scale-pans, it can be shown that the theory is not essentially different from that belonging to those of the second class.

In order to weigh any number of pounds from 1 to n inclusive, we have to factorize the expression

$$x^{-n} + x^{(-n-1)} + x^{-(n-2)} + \dots + n^{-1} + 1 + x + \dots + x^{n-2} + x^{n-1} + x^n,$$

which may be thrown into the form

$$\frac{1 - x^{2n+1}}{x^n(1-x)}.$$

The solutions depend upon the composite character of the number $2n + 1$. There always exists the trivial solution consisting of n ones, and when $2n + 1$ is prime, this constitutes the only solution.

Supposing $2n + 1$ the product of two primes, viz.

$$2n + 1 = st,$$

we may write

$$\frac{1 - x^{2n+1}}{x^n(1-x)} = \frac{1 - x^{st}}{x^n(1-x)} = \frac{1}{x^n} \cdot \frac{1-x^s}{1-x} \cdot \frac{1-x^{st}}{1-x^s}$$

$$= \frac{1-x^s}{x^{\frac{s-1}{2}}(1-x)} \cdot \frac{1-x^{st}}{x^{\frac{s(t-1)}{2}}(1-x^s)}$$

$$= \left(x^{-\frac{s-1}{2}} + x^{-\frac{s-3}{2}} + \dots + x^{-1} + 1 + x + \dots + x^{\frac{s-3}{2}} + x^{\frac{s-1}{2}}\right)$$

$$\times \left(x^{-\frac{st-s}{2}} + x^{-\frac{st-3s}{2}} + \dots + x^{-s} + 1 + x^s + \dots + x^{\frac{st-3s}{2}} + x^{\frac{st-s}{2}}\right).$$

The factors appearing in this last expression are of the required form, and the factorization indicates that any number from 1 to n inclusive may be composed by means of $\frac{1}{2}(s-1)$ ones, and $\frac{1}{2}(t-1)$ s's, if all the ones that are taken be taken *either* positively or negatively, and all the s's also *either* positively or negatively.

The solution may be represented, according to the method before explained, by

$$1^{\frac{1}{2}(s-1)}\ s^{\frac{1}{2}(t-1)},$$

and the complete system of solutions will in the present case be denoted by

$$\begin{cases} 1^{\frac{1}{2}(st-1)}, \\ 1^{\frac{1}{2}(s-1)}\ s^{\frac{1}{2}(t-1)}, \\ 1^{\frac{1}{2}(t-1)}\ t^{\frac{1}{2}(s-1)}. \end{cases}$$

From the above, it is clear that there is a one-to-one correspondence between the solutions of the second class problem in regard to the number n and the solutions of the first class problem in regard to the number $2n$. The theory of the second class problems is thus included in that of the first class problems. If we take the case considered in this journal of $n = 40$ and both scale-pans, the number of solutions will be the same as that for $n = 80$ and one scale-pan; the number depends upon the composite character of the integer 81, which is 3^4; hence the number of solutions (see *ante*) is [4], which is 2^3 or 8.

Corresponding to the several identities—

$$\frac{1-x^{81}}{x^{40}(1-x)}$$
$$= x^{-40} + x^{-39} + \dots + x^{-1} + 1 + x + \dots + x^{39} + x^{40};$$

$$\frac{1-x^{81}}{x^{39}(1-x^3)} \cdot \frac{1-x^3}{x(1-x)}$$
$$= (x^{-39} + x^{-36} + \dots + x^{-3} + 1 + x^3 + \dots + x^{36} + x^{39})(x^{-1} + 1 + x);$$

$$\frac{1-x^{81}}{x^{36}(1-x^9)} \cdot \frac{1-x^9}{x^4(1-x)}$$
$$= (x^{-36} + x^{-27} + \dots + 1 + \dots + x^{27} + x^{36})$$
$$(x^{-4} + x^{-3} + \dots + 1 + \dots + x^3 + x^4);$$

$$\frac{1-x^{81}}{x^{36}(1-x^9)} \cdot \frac{1-x^9}{x^3(1-x^3)} \cdot \frac{1-x^3}{x(1-x)}$$
$$= (x^{-36} + x^{-27} + \dots + x^{36})(x^{-3} + 1 + x^3)(x^{-1} + 1 + x);$$

$$\frac{1-x^{81}}{x^{27}(1-x^{27})} \cdot \frac{1-x^{27}}{x^{13}(1-x)}$$
$$= (x^{-27} + 1 + x^{27})(x^{-13} + x^{-12} + \dots + x^{13});$$

$$\frac{1-x^{81}}{x^{27}(1-x^{27})} \cdot \frac{1-x^{27}}{x^{12}(1-x^3)} \cdot \frac{1-x^3}{x(1-x)}$$
$$= (x^{-27} + 1 + x^{27})(x^{-12} + x^{-9} + \dots + x^{12})(x^{-1} + 1 + x);$$

$$\frac{1-x^{81}}{x^{27}(1-x^{27})} \cdot \frac{1-x^{27}}{x^9(1-x^9)} \cdot \frac{1-x^9}{x^4(1-x)}$$
$$= (x^{-27} + 1 + x^{27})(x^{-9} + 1 + x^9)(x^{-4} + x^{-3} + \dots + x^4);$$

$$\frac{1-x^{81}}{x^{27}(1-x^{27})} \cdot \frac{1-x^{27}}{x^9(1-x^9)} \cdot \frac{1-x^9}{x^3(1-x^3)} \cdot \frac{1-x^3}{x(1-x)}$$
$$= (x^{-27} + 1 + x^{27})(x^{-9} + 1 + x^9)(x^{-3} + 1 + x^3)(x^{-1} + 1 + x).$$

These are the eight solutions represented by

1^{40}
$1 . 3^{13}$
$1^4 . 9^4$
$1 . 3 . 9^4$
$1^{13} . 27$
$1 . 3^4 . 27$
$1^4 . 9 . 27$
$1 . 3 . 9 . 27.$

The subject is more fully entered into in a paper by myself in the *Quarterly Journal of Pure and Applied Mathematics* for 1886.

P. A. MACMAHON.

THE SCIENTIFIC RESULTS OF THE OCCUPATION OF BRITISH NEW GUINEA.

A VOLUMINOUS and extremely interesting report on the first year of the administration of British New Guinea by Sir William MacGregor was issued some time ago by the Colonial Office. It deals with the period ending June 30, 1889. One of the sections of the report deals with "scientific results," which we are glad to notice have a place like "finance," "legislation," "trade and shipping," and the other usual divisions of these colonial reports. In sending the report home, Sir Henry Norman, the Governor of Queensland, observes that it is fortunate that the administrator is most anxious to obtain the best scientific results on his visits and tours, and that he is well able to judge for himself in such matters. The scientific collections, therefore, are made with judgment, and the various reports on collections are of interest and value. Sir William MacGregor himself, in summing up the scientific results, says that during the year some addition was made to our knowledge of the natural history of the country. Unfortunately, it is not possible to set out fully the progress made, as the report on specimens sent to England had not reached him at the moment of writing. It is his hope, however, that in future all specimens collected may be examined in Australia, so that the information gained can be kept together and be summarized in each annual Report.

Geology.—Thirty-one small bags of specimens were examined by Mr. Jack, Government Geologist of Queensland. All except two were from the Louisiade and D'Entrecasteaux groups. Mr. Jack's report, which will be found to be interesting and valuable, is given in an appendix. A set of specimens, covering the route from Manu-Manu to the summit of the Owen Stanley Range, was submitted to careful examination by Mr. Rands, Assistant Government Geologist of Queensland, who at the same time classified the specimens collected in the Rigo district. Mr. Rand's report will also be found in an appendix. Although not forming any part of the work of the year, there is added to the same appendix a report on certain geological specimens collected by Mr. C. S. Wilkinson. These three reports practically contain all that is really known of the geology of the country.

Ornithology.—The greater portion of the birds obtained were classified by Mr. de Vis. His report, prepared after much careful labour, is added as an appendix. From it may be inferred that the probability is that no great addition will be made now to the more beautiful and gorgeous birds of British New Guinea.

Reptiles.—The reptiles collected during the latter part of the year were classified by Mr. de Vis, Director of the Queensland Museum. They include ten species of snakes. Mr. de Vis has reported that of these ten species only two, a death-adder and a whip-snake, are to be dreaded. A small batrachian, mentioned Mr. de Vis, is interesting as having been brought from the top of Mount Victoria. A note furnished by Mr. W. H. Miskin, giving the results of his examination of a collection of Lepidoptera, and a description by Mr. C. Hedley of a new Rhylida from the highest summit of the Owen Stanley Range, are also given in an appendix.

Botany.—All botanical specimens were sent to Baron Mueller. He has found time to classify the specimens forwarded to him, and his report is also included in the "White-Book." In this branch much yet remains to be done, the collecting of plants being attended with great difficulties in New Guinea. It thus appears that the scientific work is contained in a series of appendices by specialists, in the shape of reports made on the various collections of Sir William MacGregor and his officers. Appendix B is a report by Prof. Liversidge on the hot springs of Ferguson Island in the D'Entrecasteau group; while D is a very long report from Sir William MacGregor himself on a tour made by him from Manu-Manu on the coast to the Owen Stanley Range in the interior. It gives *inter alia* a fascinating description of the mountain scenery in that great range. Appendix F contains the reports of Messrs. Jack and Rands on the geological collections. Mr. Jack observes that the specimens tell no connected tale such as would enable one to construct even a theory regarding the geology of the islands. They show, however, that palæozoic rocks, such as are the matrices of gold and other metallic deposits in Australia and elsewhere, are abundant, and that basaltic lavas are of common occurrence. The limestones may yield fossils which would be of great service in unravelling the structure of the islands. Mr. Rands, to whom were submitted the specimens collected by Sir William MacGregor on his expedition up the Vanapa river to the top of Mount Victoria, says that they enable one to form an idea of the geological character of the country drained by the Vanapa. The whole region consists almost entirely of schists, which become more highly metamorphosed as the loftier heights of the Musgrave Range and Mount Victoria are reached. On Mount Victoria the schists are very numerous, highly crystalline, and closely approaching to gneiss; on passing down the river, the country consists of clay, schists, and slates; while from near the mouth there are specimens of a but slightly altered sandstone. The report of Mr. de Vis, of the Brisbane Museum, on the birds is contained in Appendix G. The collection contained 161 specimens, representing 82 species, of which 13 appear to be hitherto unrecorded; "and of the apparent novelties one at least lays claim to generic rank." This is a very distinct kind of bower bird, obtained on Mount Knutsford, at an elevation of 11,000 feet, and rivalling the Regent Bird in beauty. "The name *Cnemophilus* (Mountain-slope Lover) has been appropriated to it, and the species I propose, with permission, to dedicate to yourself [Sir William MacGregor]. A second new bower bird, constituting a third species of the genus *Amblyornis*, and distinguished by a very ornate crest, will, if allowed, be honoured with the name of Lady MacGregor. It is well to note that the diversity in the structure of the bowers of this and of the other crested species of *Amblyornis* is far greater than the differences in their personal attributes. At your request the name of Mr. Belford, one of your party, has been associated with a capture in which he was concerned, a new honeyeater, of the genus *Melirrhophetes*. A similar compliment has been paid to another member of your collecting staff, Mr. C. Kowald, in connection with the beautiful genus of flycatchers, *Todopsis*. The number of species procured during the expedition to the Owen Stanley Range was 61, eight of them being apparently new to science. The expectations of ornithologists who have for some time been awaiting the exploration of that region will thus be in some measure fulfilled, notwithstanding that no new Birds of Paradise have been discovered. Perhaps, however, the greatest interest attaching to the ornithological results obtained arise from the fact that the decided change of climate observed at the altitude attained, over 13,000 feet, is not attended by a corresponding change in the types of bird life; it would seem that there is even here no infusion of forms characterizing temperate or cold latitudes. It is true that no birds were brought down from the highest points reached, but at 13,000 feet a flycatcher was procured which is essentially Australian in type. The presence of a blackbird, now first discovered in New Guinea, is not in this connection contradictory, since the genus *Merula* is represented in other of the Pacific Islands. Some interesting additions to our knowledge of the birds of the Louisiade Archipelago result from your visits to the islands within your jurisdiction. 21 species from East, Sudest, Ferguson, Rossel, and other isles have been determined; of these several cannot be identified with species previously known, as far as I am able to judge. As these birds were procured hurriedly, they doubtless represent but a very small proportion of the several faunas. If it were possible to station a collector on one of the larger islands, Sudest, for example, so that a fairly complete knowledge of its zoology could be obtained, science would be greatly benefited." The descriptive list of the birds which follow is very full and interesting. It is succeeded by a report by the same gentleman on the reptiles collected during the expedition; they consisted of two species of lizards, ten of snakes, and one frog. The snake-like lizard (*Lialis*) is common to Australia and New Guinea; the sleeping lizard (*Cyclodus*) is in Australia represented by other species; both are perfectly harmless. Of the snakes also, the greater majority are innocuous; the death-adder (*Acanthophis*) and the whip-snake (*Diemansia*) are, indeed, the only kinds to be dreaded. With the exception of the tree-snake (*Dendrophis*) the rest are the constrictors *Liasis*, *Chondropython*, *Aspidopython*, and *Enygrus*, and the colubine snakes *Lycodon*, *Mainophis*, and *Pappohis*. It is clear that deadly snakes are not to be added to the imaginary terrors of the Papuan climate. Four of the snakes represented are Australian species. The sole exampler of the batrachians is a little frog, which Mr. de Vis regards as a new species of its genus, *Michrohyla*. This is followed by Mr. Miskin's note on the collection of Lepidoptera. He says that a glance at the specimens, confirmed upon closer inspection, conveyed the impression that they represented only the fauna of the lower altitudes, although as a fact they were collected at some distance from the coast, proving, with but two or three exceptions, to be species already known to science. Sir William was unfortunately unable to give attention to this branch of zoology during his explorations of the higher altitudes, where new forms of the greatest interest might be anticipated to occur. He observes that the collection is interesting as showing the similarity of the New Guinea fauna with that of North East Australia, there being no less than 23 of the 53 species common to both regions; while of the 31 genera represented 25 are found in both countries.

Mr. Hedley in his note on the new Rhytida says that from the highest summit (13,000 feet) of the Owen Stanley Range two land shells were brought down by Sir W. MacGregor and committed for examination to the Queensland Museum. As these are the first traces of molluscan life collected in the New Guinea mountains, and as no form at all resembling them is described by Sig. Tapparone-Canefri, he feels some confidence in deciding them to be a hitherto unknown species. More globose than other of the genus, the glossy exterior, nacreous interior, characteristic colour and sculpture, stamp it as a Rhytida; and thus another genus is added to those common to Australia and New Guinea. Though well preserved both the specimens that furnish the following description are "dead shells"; one is slightly darker and less globose than its fellow:—*Rhytida Globosa*, n.s. Shell, depressed-globose, thin, translucent, perforate, very glossy; whorls $4\frac{1}{2}$, the earlier flattened, the latter rounded, rather rapidly increasing, the last a little expanded, not descending at the aperture; colour, reddish-chestnut above, lighter beneath, first three whorls bleached nearly white; sculpture almost effaced on the body whorl, where nearly obsolete spiral impressed lines cross the faint irregular growth lines; the earlier whorls exhibit fine close oblique striae cut by fine spiral grooves, a pitted (not striated) surface is offered by the first whorl and a half, which seem embryonic; suture impressed, slightly crenulated, bordered beneath by a narrow white band, which is in turn edged by a black line; aperture ovate, oblique; peristone simple above, slightly reflected below; interior bluish-white, probably iridescent when fresh; columella wall overlaid by a thin deposit; umbilicus narrow, partially hidden by the reflected peristone at its junction with the base; base a little inflated. Greater diam. 17 mm., lesser 14 mm., height 10 mm. A report from Baron von Mueller on the Papuan Highland plants collected brings the scientific part of the "White-Book" to a conclusion. This is somewhat lengthy to reproduce in full now, and it is not easy to summarize it adequately. Readers must therefore be referred to the volume itself, where the report appears at pp. 125–129.

THE DETERMINATION OF THE WORK DONE UPON THE CORES OF IRON IN ELECTRICAL APPARATUS SUBJECT TO ALTERNATING CURRENTS.[1]

When the case is one of a transformer, the problem may be solved by the employment of three dynamometers in the way I have already pointed out; but in that of an electro-magnet, where we have only one coil to deal with, the problem still admits of solution if we further employ a condenser of determined capacity, and possess a knowledge of the period by means of some speed indicator. The plan is as follows:—

Arrangement.—Having the machine and magnet in series, insert the three dynamometers in series immediately at one terminal of the electro-magnet, placing one pole of the condenser to the other terminal, and the second pole to that point of the middle dynamometer where its two coils join.

Observations.—Obtain good simultaneous readings of the three dynamometers, and if necessary of the speed indicator.

Elements of Calculation.—Let a_1, a_2, a_3 be the angles read upon the instrument (1) in the generating section, (2) in the electro-magnet section, (3) which has its coils divided.

Let the reducing formula for the three instruments be respectively,

$$(\text{Current})^2 = k_1 \theta,$$
$$\text{,,} \quad = k_2 \theta,$$
$$\text{,,} \quad = k_3 \theta.$$

Let C be the capacity of the condenser.
R ,, ,, resistance of the electro-magnet.
T ,, ,, semi-period.

Then the entire power at work beyond the terminals, *i.e.* the heating of the wire, the heating of the core by induced currents, and the heating of the core due to hysteresis is expressed by the simple formula—

$$\frac{T}{\pi C}\sqrt{k_1 k_2 a_1 a_2 - k_3^2 a_3^2}.$$

The expression itself is independent of the resistance, but if we desire to know the power heating the core, we must deduct from the above the power heating the wire, viz.:

$$k_2 a_2 R.$$

The difference between these two quantities also happens to be proportional to the tangent of the magnetic lag, another proof of the universal concurrency of lag and loss of power.

Royal Naval College, Greenwich, October.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Dr. A. Macalister has been elected Chairman of Examiners for the Natural Sciences Tripos. Dr. C. H. Ralfe has been appointed an additional examiner in Medicine. Prof. Hughes has been elected a member of the General Board of Studies, Mr. J. Prior and Mr. C. Geldard members of the Botanic Garden Syndicate, Dr. Cayley a member of the Library Syndicate, Prof. J. J. Thomson and Mr. H. F. Newall members of the Observatory Syndicate, Dr. Bradbury and Dr. Ingle members of the State Medicine Syndicate, Mr. L. Humphry a member of the Special Board for Medicine, Mr. W. N. Shaw of the Fire Prevention Syndicate, Dr. Besant of the Mathematical Board, Mr. Newall of the Physics and Chemistry Board, and Dr. Gaskell of the Biology Board. Mr. E. H. Griffiths, Lecturer at Sidney, has been approved as a Teacher of Physics with reference to the regulations for medical degrees.

SOCIETIES AND ACADEMIES.

London.

Royal Society, November 20.—"On the Specific Heats of Gases at Constant Volume. Part I. Air, Carbon Dioxide, and Hydrogen." By J. Joly, M.A., B.E., Assistant to the Professor of Civil Engineering, Trinity College, Dublin. Communicated by Prof. Fitzgerald, M.A., F.R.S., F.T.C.D.

In this first notice the specific heats, at constant volumes, of air, carbon dioxide, and hydrogen are treated over pressures ranging from 7 to 25 atmospheres. The range of temperature is not sensibly varied. It is found that the specific heats of these gases are not constant, but are variable with the density. In the case of air the departure from constancy is small and positive; that is, the specific heat increases with increase of the density. The experiments afford directly the mean value 0·1721 for the specific heat of air at the absolute density of 0·0205, corresponding to the pressure of 19·51 atmospheres. A formula based on the variation of the specific heat with density observed in the experiments ascribes the value 0·1715 for the specific heat at the pressure of one atmosphere. The formula assumes the specific heat to be a linear function of the density, which must as yet be regarded only as an approximation, the exact nature of the relation being concealed by variations among the experiments.

These results appear to be in harmony with the experiments of Wiedemann on the specific heat at constant pressure, and of Rowland on the mechanical equivalent of heat, from which the value 0·1712 is deduced for C_v at 760 mm.

The experiments on carbon dioxide reveal a more rapid variation of the specific heat with density, the variation in this case being again positive in sign. The formula

$$C_v = \rho \times 0{\cdot}2064 + 0{\cdot}16577$$

appears with considerable reliability to express the relation between specific heat and density.

The relation between specific heat and density in the case of hydrogen is of a negative character; that is, the specific heat diminishes with increase of density. The experiments are chiefly directed to elucidate this point, for, owing to the difficulty of preparing pure hydrogen, it was found that variations in the quantitative results of experiments on different samples of the gas were unavoidable. Accordingly the experiments were directed to a comparison of the specific heats of like samples of the gas at different densities. The variation with density is small, but (with one exception) all experiments on the purer hydrogen ascribe a negative character to it.

The nature of these variations of specific heat with change of density is, in the case of the three gases, in accord with their behaviour as regards Boyle's law, within the range of pressure.

The experiments were effected in the steam calorimeter, a differential method being used in which an empty or idle vessel is thermally compared with the vessel holding the gas at high pressure. The vessels possessing approximately the same calorific capacity, the result, theoretically, is as if the gas was dealt with isolated from any containing vessel. Although practically this is not attained, many sources of error are eliminated by the procedure adopted.

November 27.—"On the Homology between Genital Ducts and Nephridia in the Oligochæta." By Frank E. Beddard, M.A., Prosector of the Zoological Society. Communicated by Prof. E. Ray Lankester, M.A., LL.D., F.R.S.

It is usually stated in text-books that the genital ducts of the Oligochæta are homologous with nephridia; but nevertheless the question is one which has not yet been satisfactorily settled, for the total independence of the two structures in *Lumbricus* and those aquatic Oligochæta of which the development is known is a difficulty in the way of accepting this view. Claparède, who first clearly formulated the arguments in favour of regarding the genital ducts as slightly modified nephridia, made a mistake in stating that the genital segments of the aquatic Oligochæta contain no nephridia; this error was pointed out by Vejdovsky, who discovered that the genital segments are originally furnished with nephridia, which atrophy on the ripening of the sexual products and the appearance of their ducts. Prof. Lankester pointed out that in *Lumbricus* the genital ducts and the nephridia have a close relation to one or other of the two pairs of setæ with which each segment is provided. He suggested that the genital ducts might represent the only portion left of a ventrally opening series of nephridia. M. Perrier's memorable investigations into the structure of exotic earthworms tended at first to confirm this theory. He discovered that in one earthworm (*Plutellus*) the nephridia alternated in position from segment to segment, thus suggesting that the supposed original two sets of nephridia had both partly persisted and partly disappeared. In other forms the nephridia were found to be related to the ventral setæ, and the genital apertures to the dorsal setæ, the exact converse of the condition which occurs in *Lumbricus*. Later investigations, however, which resulted in the discovery that the genital apertures and nephridiopores may coincide at the same setæ, led M. Perrier to abandon the hypothesis. My own discovery, first published in the Proceedings of this Society, that in *Acanthodrilus multiporus* there are more than a single pair of nephridiopores to each segment, removed the difficulties urged by Perrier. And as this discovery has been extended by myself and by others to many species and genera of earthworms, there can be no longer any intrinsic improbability in the hypothesis. The whole subject has been lately reviewed by Eisig in his treatise upon the anatomy and physiology of the Capitellidæ, which forms one of the series of monographs issued by the Zoological Station at Naples. Dr. Eisig decides that the genital ducts are probably modified nephridia in the Oligochæta; in the Capitellidæ they certainly are; but, as the Capitellidæ do not appear to me to be so nearly related to the Oligochæta as Dr. Eisig considers, I should regard this argument as only having the force that an argument from analogy can have. Since the appearance of Dr. Eisig's work, an important paper by Dr. Stolc, dealing with the generative organs of *Æolosoma*, has come into my hands; it appears that in this Annelid there are no special sperm ducts, but that the function of such ducts is performed by several pairs of nephridia. This fact, however, interesting though it is, is not a proof of the homology between sperm ducts and nephridia in other types.

I have lately had the opportunity of studying the development of the New Zealand species *Acanthodrilus multiporus*. The sum of money which the Government Grant Committee of the Royal Society were good enough to place at my disposal has enabled me to defray the expenses of this investigation.

In the young embryos of this worm each segment is furnished with a pair of nephridia, each opening by a ciliated funnel into the segment in front of that which carries the dorsally placed external pore. In later stages the funnels degenerate, and that portion of the tube which immediately follows the funnel becomes solid, losing its lumen; at the same time the nephridium branches, and communicates with the exterior by numerous pores. At a comparatively early stage, four pairs of gonads are developed in segments X.–XIII.; each of these is situated on the posterior wall of its segment, as in *Acanthodrilus annectens*, and not on the anterior wall, as in the majority of earthworms. When the gonads first appear, the nephridial funnels, with which they are in close contact, are still ciliated, and their lumen is prolonged into the nephridium for a short distance. Later the cilia are lost, and the funnels increase greatly in size, while those of neighbouring segments—in fact, all the remaining funnels—remain stationary for a time, and then become more and more degenerate. The large funnels of the genital segments become the funnels of the vasa differentia and oviducts; it will be observed that the number of ovaries and oviducal funnels (*two* pairs) at first corresponds to that of the testes and sperm duct funnels; subsequently the gonads and commencing oviducts of segment XII. atrophy. Each of these large funnels is continued into a solid rod which passes back through the septum, and then becomes continuous with a coiled tuft of tubules, in which there is an evident lumen, and which is a part of the nephridium of its segment. In the segments in front of and behind the genital segments, the rudimentary funnels communicate in the same way with a solid rod of cells which runs straight for a short distance and then becomes coiled and twisted upon itself and provided with a distinct lumen. In fact, apart from the relative size of the funnels and the presence of the gonads, it would be impossible to state from which segment a given section through the terminal portion of a nephridium had been taken. In a later stage the large funnels of the genital segments become ciliated; but this ciliation takes place before there is any marked change in the tube which is connected with the funnel.

In the young worm which has just escaped from the cocoon the funnels are ciliated, and they are each of them connected by a short tube, in which a lumen has been developed, but which ends blindly in close proximity to a coil of nephridia. No trace of any nephridial tube other than the sperm duct or oviduct could be observed, whereas in the preceding and succeeding segments the rudimentary nephridial funnel, and a straight tube leading from it direct to the body wall, was perfectly plain. Dr. Bergh has figured, in his account of the development of the generative organs of *Lumbricus*, a nephridial funnel in close contact with the funnel of the genital duct. It may be suggested that a corresponding funnel has been overlooked in the embryo *Acanthodrilus*; the continuity of a structure, identical (at first) with the nephridia of the segments in front and behind, with the genital funnels, seems to show that a search for a small nephridial funnel would be fruitless.

I can only explain these facts by the supposition that *in Acanthodrilus multiporus the genital funnels and a portion at least of the ducts are formed out of nephridia*. This mode of development is a confirmation, to me unexpected, of Balfour's suggestion that in the Oligochæta the nephridium is broken up into a genital and an excretory portion.

In the comparison of the facts, briefly described here, with the apparently independent origin of the generative ducts in other Oligochæta, it must be borne in mind that in *Acanthodrilus* the segregation of the nephridium into several almost detached tracts communicating with the exterior by their own ducts precedes the formation of the genital ducts.

"The Patterns in Thumb and Finger Marks: on their Arrangement into naturally distinct Classes, the Permanence of the Papillary Ridges that make them, and the Resemblance of their Classes to ordinary Genera." By Francis Galton, F.R.S.

The memoir describes the results of a recent inquiry into the patterns formed by the papillary ridges upon the bulbs of the thumbs and fingers of different persons. The points especially dwelt upon in it are the natural classification of the patterns, their permanence throughout life, and the apt confirmation they afford of the opinion that the genera of plants and animals may be isolated from one another otherwise than through the influence of natural selection.

The origin of the patterns was shown to be due to the existence of the nail, which interfered with the horizontal course of the papillary ridges, and caused those near the tip to run in arches, leaving an interspace between them and the horizontal ridges below. This interspace was filled with various scrolls which formed the patterns. The points or point at which the ridges diverged to inclose the interspace were cardinal points in the classification. It was shown that there were in all only nine possible ways in which the main features of the inclosure of the interspace could be effected. In addition to the nine classes there was a primary form, occurring in about 3 per cent. of all the cases, in which the interspace was not clearly marked, and from this primary form all the other patterns were evolved. The forms of the patterns were easily traced in individual cases by following the two pair of divergent ridges, or the one pair if there was only one pair, to their terminations, pursuing the innermost branch whenever the ridge bifurcated, and continuing in an adjacent ridge whenever the one that was being followed happened to come to an end. Twenty-five of the principal patterns were submitted, and a few varieties of some of them, making a total of forty. They are by no means equally frequent.

The data as to the permanence of the patterns and of the ridges that compose them were supplied to the author by Sir W. J. Herschel, who, when in the Indian Civil Service, introduced in his district the practice of impressing finger marks as a check against personation. Impressions made by one or two fingers of four adults about thirty years ago, and of a boy nine years ago, are compared with their present impressions. There are eight pairs of impressions altogether, and it is shown that out of a total of 296 definite points of comparison which they afford, namely the places where ridges cease, not one failed to exist in both impressions of the same set. In making this comparison no regard was paid to the manner in which the several ridges appear to come to an end, whether abruptly or by junction with another ridge. The reason was partly because the neck where junction takes place is often low, and may fail to leave a mark in one of the impressions.

Lastly, the various patterns were shown to be central typical forms from which individual varieties departed to various degrees with a diminishing frequency in each more distant degree, whose rate was in fair accordance with the theoretical law of frequency of error. Consequently, wide departures were extremely rare, and the several patterns corresponded to the centres of isolated groups, whose isolation was not absolutely complete, nor was it due to any rounding off by defined boundaries, but to the great rarity of transitional cases. This condition was brought about by internal causes only, without the least help from natural selection, whether sexual or other. The distribution of individual varieties of the same patterns about their respective typical centres was precisely analogous in its form, say, to that of the shrimps about theirs, as described in a recent memoir by Mr. Weldon (Roy. Soc. Proc., No. 291, p. 445). It was argued from this, that natural selection has no monopoly of influence either in creating genera or in maintaining their purity.

"The Conditions of Chemical Change between Nitric Acid and certain Metals." By V. H. Veley, M.A.

This paper is in continuation of a preliminary communication on the same subject. The main points contained in it are as follows:—

(1) The metals copper, mercury, and bismuth do not dissolve in nitric acid of about 30 per cent. concentration (the acid commonly employed for the preparation of nitric oxide gas) and heated to a temperature of 30° C., provided that nitrous acid is neither present initially nor formed subsequently. To prevent this, it is necessary in the cases of copper and bismuth to add a small quantity of some oxidizing substance, such as hydrogen peroxide or potassium chlorate, or, as less efficacious, potassium permanganate, or to pass a current of air, or, lastly, such a substance as urea, which destroys the nitrous acid by its interaction.

(2) If the conditions are such that these metals dissolve, then the amount of metal dissolved and the amount of nitrous acid present are concomitant variables, provided that the nitric acid is in considerable excess. Change of conditions, such as concentration of acid and variation of temperature, which increase the former increase also the latter.

(3) If the conditions are such that these metals dissolve, it would appear that the metallic nitrite is at first formed, together with nitric oxide; the former is decomposed by the excess of nitric acid to liberate nitrous acid, while the latter reduces the nitric acid to form a further quantity of nitrous acid.

Eventually the net result is the product of two reverse chemical changes represented by the equations:—

$$\text{(i.)}\ 2NO + HNO_3 + H_2O = 3HNO_2,$$
$$\text{(ii.)}\ 3HNO_2 = 2NO + HNO_3 + H_2O.$$

The nitrous acid is thus destroyed as fast as it is generated.

(4) If the conditions are such that metals dissolve in nitric acid, then nitrous acid is invariably the initial product of reduction.

(5) The metals copper, mercury, and bismuth dissolve very readily in a 1 per cent. solution of nitrous acid; under these conditions nitric acid present in slight excess interferes with, rather than promotes, the chemical change. This result is probably due to the greater stability of nitrous acid in the presence of nitric acid.

(6) Hydrogen gas reduces nitric to nitrous acid in presence of cupric or lead nitrate; it also converts mercuric into mercurous nitrate, but does not produce any change in solutions of bismuth and zinc nitrates dissolved in nitric acid.

Physical Society, November 14.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—The following communications were made:—On certain relations existing among the refractive indices of the chemical elements, by the Rev. T. Pelham Dale. The first part of the paper corroborates the results announced in a communication made in May 1889 on the same subject, and says that as far as experimental data are forthcoming the refraction $(\mu - 1)$ divided by the vapour density (d) is equal to a constant multiplied by some integer. Several metals whose refractions have since been determined conform to this law. On examining the relation between molecular weight (M) and refraction, similar conclusions are arrived at; for to a fair degree of approximation the ratio $M/(\mu - 1)$ is a constant, or a simple multiple of this constant. The question as to how far the relation $(\mu - 1)/d = c$ holds good for the same element in the three states of vapour, liquid, and solid, has been examined as far as data exist for this purpose. The resulting numbers are not identical, but some of the data themselves are doubtful. Another relation is between the molecular distances (h) (see Proc. Phys. Soc., vol. ix. p. 167) and the atomic weight (a) of the elements, h being nearly proportional to $\sqrt{a}$. In the case of selenium, sulphur, and phosphorus, the agreement is close, but for bromine, chlorine, and carbon, not so good. A fifth relation appears to exist between the upper limit of refraction and the line spectra of elements. For example, the upper limit of refraction for selenium occurs at wave-length 5295·7, whilst its spectrum exhibits a remarkable series of strong lines about this wave-length. A similar relation apparently holds with sulphur, phosphorus, and bromine. Gold also shows a series of strong lines about c, in the vicinity of which the metal has the greatest reflective power. The author finds that selenium polarizes and reflects nearly all the light that falls on it at a large angle, and suggests that it may be used in polariscopes. He has also endeavoured to connect together the phenomena of a limit of refraction and anomalous dispersion. In the case of fuchsin the dark space coincides with the limit of refraction, and the same is probably true of cyanin. If one of the anomalous indices be given the other can be found. He also believes that bodies of high molecular weight give anomalous dispersion, and thinks solutions of iodine will exhibit the phenomenon. The mathematical investigation of the whole subject involved difficulties arising from the want of trustworthy data, and the author hopes that some member will take up the necessary experimental determinations. Dr. Gladstone thought the author under-estimated the amount of work done and in progress on the subject, for the question whether $(\mu - 1)/d$ is constant or not is being investigated by many. The French physicists, he said, had found the quantity nearly constant, but Lorenz's expression $(\mu^2 - 1)/(\mu^2 + 2)$ is slightly better when applied to compounds in the liquid and gaseous states. Metals were difficult to deal with, especially as, according to the recent paper of Du Bois and Reubens, their refractions do not follow the law of sines. Mr. Dale here suggested that they might be related to hyperbolic sines. Dr. Gladstone, continuing, said that, by taking solutions of metals, it was found that their specific refractive energies were nearly inversely as the square roots of their combining weights, but at present the known cases were not sufficient to establish a law. Prof. Rücker said that of the two expressions, $(\mu - 1)/d$ and $(\mu^2 - 1)/(\mu^2 + 2)$, the latter seemed preferable, for it could be converted into electrical quantities by writing K for μ^2. The expression then becomes $(K - 1)/(K + 2)$, and if this can be shown to be constant by electrical work, this would be an argument in its favour. On the subject of anomalous dispersion he directed Mr. Dale's attention to Mr. Glazebrook's Report on Optical Theory made to the British Association. Mr. Dale, in reply, pointed out that, from the nature of the two formulæ, any inaccuracy or variation in μ would affect theirs more than Lorenz's. He also thought that $(\mu - 1)/d$ was a limit towards which the numbers tend.—Tables of spherical harmonics, with examples of their practical use, by Prof. J. Perry, F.R.S. The author defined a spherical harmonic as a homogeneous function of x, y, z, satisfying the equation—

$$\frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} + \frac{d^2V}{dz^2} = 0,$$

stated the fundamental properties of such functions, and pointed out their importance in problems on heat, electricity, and hydrodynamics. Referring to zonal harmonics (homogeneous functions of $(x^2 + y^2)^{\frac{1}{2}}$ and z), he showed that these harmonics are symmetrical with respect to the axis of z, and might be expressed as functions of the angle (θ) which the line joining the point (x, y, z) to the origin makes with the axis of z, multiplied by r^i; where r is the radius-vector and i the degree of the homogeneous function. These functions of θ are called zonal surface harmonics, and are designated by $P_0, P_1, P_2, \ldots P_i$, according to the degree of the function, and it was the values of these quantities which form the tables brought before the Society. The tables comprise the values of P_1 to P_8, and are calculated to 4 places of decimals and for every 1° between 0° and 90°. As an example of the use of such tables, the case of a spherical surface covered with attracting matter whose density varied as the square of its distance from a diametral plane was taken. It was required to find the potential both outside and inside the sphere, and to determine the equipotential surfaces and lines of force. The potentials inside (A) and outside (B) were shown to be given by

$$\frac{A}{\pi} = 8 + \frac{16}{5} r^2 P_2 \quad \text{and} \quad \frac{B}{\pi} = \frac{8}{r} + \frac{16}{5} \frac{1}{r^3} P_2$$

respectively. By giving A and B definite values, and choosing values of r, the corresponding P_2's can be calculated, and the value of θ determined from the tables. Hence any equipotential surface can be easily determined, and lines drawn to cut these surfaces orthogonally are lines of force. Another problem which had been tried consisted in finding the directions of the lines of force near a circular coil of rectangular cross-section when an electric current circulates in the coil. This was treated approximately by first calculating the potential at 6 points along the axis in the neighbourhood of the coil, and then finding by Gauss's method the coefficients A_0, A_1, A_2, &c., of an expression in ascending powers of z which agreed with the calculated potentials at the points chosen. The formula

$$V = A_0 + A_1 r P_1 + A_2 r^2 P_2 + \&c.,$$

or its corresponding expression in inverse powers of r, was then assumed to give the potential at any point in the space considered. By giving V definite values, a series of equipotential surfaces were determined, and the lines of force drawn. On putting the calculations to the test of experiment, the approximate solution of this very difficult problem was found to be very nearly correct.

Linnean Society, November 20.—Prof. Stewart, President, in the chair.—Mr. G. Murray exhibited specimens of a fresh-water *Delesseria* previously unknown.—On behalf of Mr. Henry Hutton, of Cape Town, Mr. B. D. Jackson exhibited some follicles and seeds of a somewhat rare Asclepiad (*Dregia floribunda*); and showed also, on behalf of Mr. W. Matchwick, some ripened seeds ot *Ailanthus glandulosa* from a tree at Reigate said to be a hundred years old.—Prof. Bower exhibited several drawings from microscopic sections of Carboniferous nodules belonging to Prof. Williamson, and pointed out the peculiarities of structure. Microscopic details of such sporangia being very rare, he remarked that a comparison of the slides showed a peculiar uniformity of type. For comparison with these sporangia from the coal, he exhibited sections of the sporangia of *Todea barbara*, and while not going so far as to refer these Carboniferous sporangia (which are not attached to the plants which bore them) to any distinct genus, he thought the Osmundaceous affinity was unmistakable.—Mr. J. E. Harting exhibited some original MSS. and water-colour sketches of birds, fishes, and plants, found in Sussex by William Markwick, the friend and correspondent of Gilbert White, of Selborne, which had been presented by him to the Society in his lifetime, and had been lost sight of for many years. The drawings are sufficiently well executed to enable the correct determination of several species which the author had failed to identify.—A paper was read by Prof. T. Johnson, of Dublin, on *Punctaria*, a genus of brown seaweeds (*Phæophyceæ*). He described in detail the formation of the plantlets by trichothallic germination from the tufts of primary hairs and from the secondary hairs formed on epicortical filaments on the old thallus of *P. plantaginea* and *P. latifolia*. He pointed out that neither the nature of the dots nor the position of the sporangia is of specific value, and that sporangiferous and plant-forming hairs are to be found on the filamentous root-disk of *P. tenuissima*, Grev., which, he maintained, is the young state of one species, of which *plantaginea* and *latifolia* are the more mature growths.—Mr. Vaughan Jennings gave an abstract of a paper on a variety of sponge, *Alectona millari*, Carter, boring in the shell of *Lima excavata*, from the Norwegian coast. The sponge had endeavoured to grow inwards, dissolving the nacreous layer and encroaching on the mollusk, instead of restricting its wanderings to the thickness of the shell. The mollusk had retaliated by depositing fresh layers on the intruder, and the struggle had gone on until the chambers were several times the normal thickness of the shell, and were roofed over by a thin curved layer of secondary shell substance, while the points at which branches had been pushed further in were represented by thick conical papillæ.

CAMBRIDGE.

Philosophical Society, November 10.—Prof. Darwin, President, in the chair.—The following commuications were made:—Note on the principle upon which Fahrenheit constructed his thermometrical scale, by Arthur Gamgee, F.R.S., Emeritus Professor of Physiology in the Owens College (Victoria University). The author commenced by drawing attention to the fact that, although the Fahrenheit thermometer has been so generally used in England, no accurate information was to be found in our text-books concerning the principles upon which its scale had originally been constructed. He referred, however, to a view advanced by Prof. P. G. Tait in his elementary treatise on "Heat," and which had been accepted by many teachers, according to which Fahrenheit divided his scale between 32° and 212° into 180 degrees, in imitation of the division of a semicircle into 180 degrees of arc. This theory rested on the incorrect supposition that, before Fahrenheit's time, Newton had suggested, as a basis for a thermometric scale, the fixing of the freezing and boiling points of water, the space between these being divided into a number of equal degrees. The author pointed out that in his "Scala graduum caloris," Newton made no such suggestion as that attributed to him by Prof. Tait, and prior to him by Prof. Clerk Maxwell; and, indeed, that Fahrenheit had settled the basis of his scale and had constructed a large number of thermometers, which were used by scientific men throughout Europe, many years before the discovery by Amanton (which Fahrenheit confirmed and gave precision to) of the fact that under a constant pressure the boiling point of water is constant. The author stated that the thermometers which were first constructed by Fahrenheit were sealed alcoholic thermometers, provided with a scale in which two points had been fixed. The zero of the scale, representing the lowest attainable temperature, was found by plunging the bulb of the thermometer in a mixture of ice and salt, whilst the higher of the two points was fixed by placing the thermometers under the armpit or inside the mouth of a healthy man. The interval between these two points was, in the first instance, divided into 24 divisions, each of which corresponded to supposed well-characterized differences in temperature, and each being subdivided into four. In his later alcoholic and mercurial thermometers, the 24 principal divisions were suppressed in favour of a scale in which 96 degrees intervened between zero and the temperature of man; in these later thermometers the 32nd degree was fixed by plunging the bulb of the thermometer in melting ice. The author then pointed out that Fahrenheit was led to construct mercurial thermometers in order to be able to ascertain the boiling point of water; with this object the scale, constructed as has been stated, was continued upwards, in some cases so as to include 600 degrees. It was *as the result of experiment alone*, that the number 212 was obtained as the temperature at which water boils, at the mean, atmospheric pressure. The author in conclusion argued that Fahrenheit took as the basis of his thermometric scale the duodecimal scale, which he was constantly in the habit of employing.—On variations in the floral symmetry of certain plants with irregular corollas, by Mr. W. Bateson and Miss A. Bateson.—On the nature of the relation between the size of certain animals and the size and number of their sense-organs, by H. H. Brindley. In speculation as to the evolution of various forms, it is generally held as a principle that the conditions of the struggle for existence are such that variations in the direction of atrophy or diminution in bulk of a useless organ must necessarily be beneficial by reason of the saving of tissue and effort which is effected by this reduction. It has been assumed by many that this benefit must be so marked as to lead to the natural selection of the individuals thus varying. This principle has been invoked especially in the case of sense-organs, and, for example, it has been suggested that the blindness of cave-fauna may have come about by its operation. With the object of testing the truth of this assumption, it seemed desirable to obtain a knowledge of the normal variations in size and number of sense-organs occurring within the limits of a single species. The cases chosen were (1) the olfactory organ of fishes (eel, loach, *Pleuronectidæ*, &c.), and (2) the eyes of *Pecten opercularis*. In the first case tables were given showing that large individual fluctuations occur, but that on the whole the number of olfactory plates increases with the size of the body; and it was pointed out that a similar relation holds with regard to the eyes of fishes. In the case of *Pecten*, however, though the *size* of the eyes increases with the diameter of the animal, yet in specimens having a diameter of 3 cm. to 6 cm. the *number* of the eyes is not thus related (cp. Patten), but varies in a most surprising and, as it were, uncontrolled manner. Statistics were given showing that, in individuals of the same size, the number of eyes may vary between 70 and 100, and that no uniformity is to be found. It was pointed out that these eyes are large and complicated organs, having lens, retina, tapetum, &c., involving great cost in their production. These facts suggest that the "economy of growth" cannot be a principle of such precise and rigid character as to warrant its employment as a basis for speculation as to the mode of evolution of a species. The diverse results in the case of the two sets of organs examined further indicate that the problem is one of far greater complexity, and shows clearly that argument from analogy is inadmissible in these cases.—On the oviposition of *Agelena labyrinthica*, by C. Warburton. The oviposition and cocooning of *Agelena labyrinthica* is a striking case of the performance of a series of complicated operations in obedience to a blind instinct. The eggs are always laid at night, but the presence of artificial light is quite disregarded by the animal. For about 24 hours before laying, the spider is engaged in preparing a chamber for the purpose. Near its roof a small sheet is then formed, and the eggs are laid upwards against it and are covered with silk. A box is then constructed with this sheet as its roof, and is firmly attached by its angles to the roof and floor of the chamber. This box is constructed and jealously guarded even if the eggs are removed immediately on oviposition. The whole operation involves about 36 hours of almost incessant industry.—Supplementary list of spiders taken in the neighbourhood of Cambridge, by C. Warburton.

PARIS.

Academy of Sciences, November 24.—M. Hermite in the chair.—Experiments on the mechanical actions exerted on rocks by gas at a high pressure and in rapid motion, by M. Daubrée. The working of diamond mines in South Africa has revealed the existence of vertical canals or chimneys in the earth's crust. All these chimneys are circular or elliptical in section. Their diameter varies from 20 metres to 450 metres, and is generally comprised between 150 metres and 300 metres. Their depth is considerably greater. M. Daubrée finds that he can produce precisely similar formations by means of the gas evolved when dynamite or gun-cotton is exploded, and therefore believes that the chimneys referred to are produced by the action of gases at high pressures and velocities. That the effect may be considerable is evident from a consideration of the action of gases at high pressure upon the meteorites that traverse our atmosphere.—On some facts relative to the history of carbon, by MM. Paul and Léon Schutzenberger.—On the relation of the circumference to the diameter, by Prof. Sylvester. Lambert has shown that π cannot be the square root of a whole number. The author proves that π cannot be the root of a rational equation.—Observations of Zona's comet (November 15, 1890) made at Paris Observatory with the West Tower equatorial, by M. G. Bigourdan. Three observations for position were made on November 21.—Observation of the same comet made with the East Tower equatorial, by Mdlle. D. Klumpke. An observation for position was made on November 21.—Generalization of one of Abel's theorems, by M. Albert La Maestra.—Variations of conductivity under different electrical influences, by M. Ed. Branly. If a circuit be formed with a Daniell's cell, a high resistance galvanometer, and a very thin layer of copper deposited on a ground glass or ebonite plate, 7 cm. long and 2 cm. wide, only an insignificant current passes. An abrupt diminution of resistance is experienced, however, when one or more electric discharges, from a Wimshurst machine or a Ruhmkorff's coil, are produced in the neighbourhood of the circuit. The action diminishes as the distance of the sparking apparatus increases, but it may be very easily observed, without special precautions, at several metres. The author has examined the conditions necessary to produce the observed phenomena.—Periodic visibility of interference fringes, by M. Charles Fabry.—On the artificial production of a chromium blue, by M. Jules Garnier. By heating in a brasqued crucible a mixture of K_2CrO_4 48·62 grammes, fluor spar 65 grammes, and silica 157 grammes, the author obtained a blue glass, the colour of which he attributes to reducing action taking place at a high temperature in the chromium salt.—Researches on the application of the measure of rotatory power to the determination of combinations formed by aqueous solutions of malic acid with the double molybdate of potassium and sodium, and the acid molybdate of sodium, by M. D. Gernez.—On the employment of the potato in the agricultural distillery in France, by M. Aimé Girard. The French potato crop in 1890 was remarkable for quantity and quality. The author urges the application of these crops to the production of alcohol, and experimentally proves that such a use may be commercially successful.—On the spermatozoa of Locustides, by M. Armand Sabatier.—On *Cyclatella annelidicola* (van Beneden and Hesse), by M. Henri Prouho.—On the destruction of *Heterodera schachtii*, by M. Willot.—On an eruptive rock from Ariège, and on the transformation of felspar into wernerite, by M. A. Lacroix.—On a tornado observed at Fourchambault (Nièvre), by M. Doumet-Adanson.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* from January to June 1890, contain the following papers of scientific interest:—

January.—B. Galitzine, on Dalton's law. The author reviews the different estimates taken of Dalton's law, and concludes from his experiments that it is not accurately true either as regards the resultant pressure of a mixture of gases, or as regards the pressure of vapours.

February.—Nernst, on a new principle in the determination of molecular weights. The author gives the results of experiments conducted to verify the familiar formula $a - a'/a' = n/100$.

March.—Felix Klein, on the theory of Lamé's functions. This is an account of lectures in continuation of previous courses, and is concerned with the extension of Lamé's equation, the replacing of his functions by algebraic forms, and the conformable representation of a quotient of two solutions. Hertz, on the fundamental equations of electrodynamics. This is an attempt to explain the method of proof and the significance of Maxwell's equations.

May.—Voigt, on the coincidence of two simple tones—being a reconciliation of the formulæ obtained by Helmholtz and R. König. Hartlaub, contribution to the knowledge of the *Comatulidæ* of the Indian Archipelago. Riecke, the pyro-electricity of tourmaline. The object is twofold—to examine the correctness of the formula $\epsilon = E(1 - e^{-at})$ for the electric charge during the cooling (where t denotes the time), and to find the dependence upon the difference of the initial and final temperatures of the electricity developed during the cooling.

THURSDAY, DECEMBER 11, 1890.

A CURE FOR TETANUS AND DIPHTHERIA.

THE greatest interest has been aroused in scientific circles in Berlin by a paper in the current number of the *Deutsche medicinische Wochenschrift*[1] by Behring and Kitasato. These well-known bacteriologists, who for a long time past have been working in Dr. Koch's Hygienisches Institut, have not only succeeded in producing immunity against diphtheria and tetanus, but also in curing animals already infected by these diseases. Their results are to a great extent self-explanatory, and there is every reason to expect that the same method will be found to be applicable to other infectious diseases. The most remarkable part of their discovery is the fact that the blood of an animal that has been made immune against diphtheria possesses the extraordinary power of destroying the poison formed by the microbe of this disease. This power is also possessed by the serum of such an immune animal, which serum can therefore be used as a curative means on other animals that are suffering from this disease. The same statement holds good for tetanus.

Before describing in detail these interesting results, it will be well to give a short historical review of some recent bacteriological work which can be regarded as having led up to this discovery.

Towards the end of 1888 Nuttall,[2] working in Flugge's laboratory at Breslau, discovered that various bacteria are destroyed when mixed with fresh blood or blood-serum, and further that this destruction cannot be ascribed to the action of cellular elements, but rather to the fluid part of the blood. This discovery (which really arose from the German criticism of Metschnikoff's phagocyte theory) was soon followed by the work of Buchner[3] and Nissen[4] on the bacteria-killing power of the cell-free blood-serum. These authors considered that their work necessitated a limitation of the phagocyte theory, and suggested a new view of the nature of immunity, whether natural or acquired. In other words, they suggested that immunity was conditioned by the bacteria-killing power of the various body fluids rather than by that of any particular kind of cell. These opinions were rather severely criticised in a paper by Lubarsch[5] that was published towards the end of last year. Lubarsch emphasized the fact that while the serum of the rabbit—an animal extremely sensitive to anthrax, has a great power of destroying anthrax-bacilli, horses' serum has no such power, although this animal is comparatively refractory to the disease. Again, while on the one hand such eminently pathogenic microbes as the anthrax and cholera bacilli are capable of being destroyed by serum from various animals, several perfectly harmless microbes find blood-serum to be an excellent food-medium. Further, though the serum of the rabbit kills anthrax bacilli in a pre-eminent degree, the living blood-plasma of this animal can only do so to an infinitesimal extent. Such considerations suggested to Lubarsch that the bacteria-killing power of the blood-serum was a fact rather of the nature of an epi-phenomenon than an essential factor in the conflict between the organism and the microbe. In May of this year appeared my own work on "Defensive Proteids."[1] I gave this name to a new class of proteid bodies, which I found to possess a bacteria-killing power, and which I have obtained from the spleens and lymphatic glands of various animals. This work has a distinct bearing on the foregoing, in that it suggests that the bacteria-killing power of blood-serum is due to minute traces of these substances liberated from the breaking down of lymphatic cells. The absence of a bacteria-killing power from certain kinds of serum (*e.g.* horse) and from living blood-plasma (as has been shown for that of the rabbit in regard to anthrax), appears to be connected with the intactness of the leucocytes in these special cases. Further, the fact that I obtained these substances from cells which either are, or can become, phagocytes, may be taken as an additional proof of Metschnikoff's well-known theory. These substances appear to be absent from the normal blood-plasma, or, at any rate, only present in such small quantities that they cannot be separated from it. With blood of febrile animals, however, the case is different, and from such blood I have been able to isolate a bacteria-killing substance.[2] This fact appears to indicate that these substances are actually used by the organism in its reaction against the attack of pathogenic microbes.

During last summer, while I have been engaged in this work, various other papers have appeared, which tend to show still more clearly that the bacteria-killing power of the blood serum (or if my work be accepted, of defensive proteids) is of real importance in the production of immunity. Bouchard[3] was, I think, the first of many authors who have succeeded in showing that the bacteria-destroying power of blood-serum from immune animals, is greater than that of normal serum. Bouchard proved this in the case of bacillus pyocyaneus for rabbits. He made the animals immune by injections of sterilized culture fluids, and found that serum from such animals exerted a far greater "bactericidal" action on the microbe in question than serum from a normal animal. Behring and Nissen,[4] in a paper published in May of this year, went a step further. They showed that whereas blood serum from an animal made immune against anthrax exerted an increased bactericidal action on the anthrax bacillus, it showed no increased action on the bacillus pyocyaneus. Conversely blood-serum from an animal made immune against the latter microbe, had no increased action on the anthrax bacillus, though it exerted a powerful bacteria-killing action on pyocyaneus. The authors considered that they had proved the ex-

istence of two bodies, each having a specific action on one of the two microbes in question; and further that these substances are present in animals made immune against the above-named diseases. These remarkable conclusions acquire a still greater interest when received in the light of a research by Gamaleia published at the beginning of last year.[1] Gamaleia found that the aqueous humour of a sheep, about three days after inoculation with attenuated anthrax, acquires bactericidal properties for this microbe. This condition lasts for nearly a month, and then gradually vanishes, though, as is well known, the sheep remains immune for a far longer period. These researches, therefore, suggest, firstly, that when an animal has been made immune against a pathogenic microbe, its blood and other body fluids contain a substance capable of destroying the microbe in question; secondly, it follows that such protective substances can remain in the body undestroyed for a considerable time; and thirdly, that they can be present in such quantities as to be able to kill the microbes involved (even without the help of living cells) and yet produce no appreciable ill effect on the general health of the animal. If this is so, why should it not be possible to cure any infectious disease by injecting a "lymph" obtained from the blood or tissues of an animal previously made refractory to the disease in question?

Whether or not the above considerations stimulated the researches of Behring and Kitasato, their work affords a positive answer to this question, which promises to be of the greatest importance to humanity, and has led them to the most unexpected and interesting results from the scientific standpoint. The following is a summary of their paper, which is of the nature of a preliminary communication.[2] The method by which, in the first case, they produced immunity against tetanus and diphtheria is not described. Only so much of their results is communicated as is necessary to support the following propositions:—

"The immunity of rabbits and mice against tetanus depends on the power possessed by the fluid part of their blood of rendering harmless the poisonous substances produced by the tetanus bacilli."

This proposition involves a completely new theory of the nature of acquired immunity. Hitherto it has been thought that immunity must depend either on the voracious activity of phagocytes, or on the above-mentioned bacteria-killing power of the blood, or on an acquired tolerance against a poison; and, further, that by the method of residues, any one of these theories could be proved by showing the other two to be false.

Behring, however, was able to prove, by his work on diphtheria, that none of these theories would account for the natural immunity of rats or the artificially-produced immunity of guinea-pigs against this disease. After disproving many speculations on this subject, the above-given explanation was arrived at, but they only obtained a satisfactory proof of its correctness when they began to test it on the tetanus microbe.

Their experiments prove:—

(1) That the blood of rabbits which have been made immune against tetanus can destroy the tetanus poison.

[1] "Sur la Destruction des Microbes dans les Corps des Animaux Fébricitants" (*Annales de l'Institut Pasteur*, 1889, p. 229).

[2] A fuller account will shortly appear in the *Zeitschrift für Hygiene*.

(2) This character can be shown to be possessed by the blood both before and after it has left the vessels, and in the cell-free blood-serum obtained from it.

(3) This character is of so permanent a nature that it is still manifested by such serum after it has been injected into other animals. Consequently, by transfusion of such blood or serum, important therapeutic actions can be obtained.

(4) This power of destroying the tetanus poison is absent from the blood of such animals as are not immune against tetanus; and after such animals have been killed by the tetanus poison, it can be shown to be present in their blood and tissues.

In support of these assertions the following experimental results are brought forward.

A rabbit was made immune against tetanus by a method which will be described in a forthcoming paper by Kitasato in the *Zeitschrift für Hygiene*. To prove the completeness of its immunity, 10 c.c. of a virulent culture was injected into it. Half a cubic centimetre of the same culture was quite sufficient to produce tetanus in a normal rabbit. The treated rabbit, however, remained immune, and it not only showed immunity against the tetanus bacillus, but also against the poison produced by this microbe. For it remained unharmed by an injection of twenty times the quantity of tetanus poison which will kill with certainty a normal rabbit. Blood was taken from the carotid artery of this rabbit. Before clotting occurred 0·2 c.c. of this blood was injected into the body cavity of a mouse, and 0·5 c.c. into that of another. Twenty-four hours later, these mice, together with two control-mice, were inoculated with tetanus of such virulence that the latter showed the symptoms of tetanus after 20 hours, and were dead in 36 hours. Both of the treated mice, on the contrary, remained healthy.

The greater quantity of the blood of this rabbit was allowed to stand, and its serum collected.

Six mice each received 2 c.c. of this serum in the abdominal cavity, and all withstood a subsequent inoculation with tetanus. Control-mice died of tetanus within forty-eight hours.

With this serum the authors succeeded in curing animals that had been previously infected with tetanus. They have also been able to show that this serum possesses an intense power of destroying the tetanus-poison.

Of a ten-days old tetanus culture which had been sterilized by filtering, 0·00005 c.c. was enough to kill a mouse after four to six days, and 0·0001 would always produce the same result in less than two days.

Five c.c. of the serum of a tetanus-immune rabbit was mixed with 1 c.c. of this filtered-culture, and kept for twenty-four hours. Of this mixture four mice each received 0·2 c.c. (that is to say, 0·033 of the original culture, or more than 300 times the quantity which would otherwise be capable of killing a mouse). All these four mice remained in good health. Control-mice, on the contrary, which were at the same time inoculated with 0·0001 c.c. of the original culture, succumbed within thirty-six hours.

All the mice mentioned in each of the above series of experiments have been subjected to repeated injections with the tetanus bacilli, and have shown themselves to be permanently and completely immune.

This result is the more remarkable in that up till now, in spite of innumerable attempts, no one has ever succeeded in making any animal whatever immune against tetanus. A theory of the nature of acquired immunity which at once led to a method of treating the disease which is easy to understand, harmless to the animal, and certain in its effect, must surely possess some basis in fact.

Naturally every kind of control experiment with serum of normal rabbits has been carried out with uniformly negative results. Serum of cattle, horses, and sheep has also been found to have no action on the tetanus poison. The living blood and tissues of an animal which has not been made immune likewise show no power of destroying the tetanus poison, as appears from the following experiment, which has been many times repeated:—

Rabbits into which 0·5 c.c. of a germ-free tetanus culture is injected subcutaneously, succumb after showing typical tetanus symptoms; almost always a serous transudation is to be found in the thoracic cavity. Of this transudation, 0·3 c.c. is on the average enough to kill a mouse with typical tetanus symptoms. The same is true for the blood.

The authors close their paper by pointing out the possibility that their method of curing tetanus and diphtheria which they have used with such brilliant results on animals so highly susceptible to these diseases as mice and rabbits, may also be used for the far less susceptible hospital patient. They also note the possible influence of their work on the practice of blood-transfusion.

E. H. HANKIN.

THE STEAM-ENGINE.

The Steam-Engine considered as a Thermodynamic Engine. A Treatise on the Thermodynamic Efficiency of Steam-Engines, illustrated by Diagrams, Tables, and Examples from Practice. By James H. Cotterill, M.A., F.R.S., Professor of Applied Mechanics in the Royal Naval College. Second Edition, revised and enlarged. (London: E. and F. N. Spon, 1890.)

IN view of the general interest attaching to the recent improvements in steam-engines, and the consequent gain so remarkably illustrated by the increased speeds of ocean travel, an exposition from a purely scientific point of view of the causes of this progress comes at a very opportune time. The book before us is the second edition of a treatise which was originally published in the year 1877, and has since that time remained one of the chief authorities on the practical applications of thermodynamics.

It seems to be inherent in the industrial development of scientific laws that the course of invention should occasionally lead engineers away from the principles of pure science on which their work is based. The minds of inventors often become so much occupied with the intricate and perplexing problems presented by the mechanical realization of their ideas, that in the specifications of their successful arrangements, the naked principles which are the common and essential part of all practice are sunk far beneath the surface. It is of no ordinary importance that means should exist for co-ordinating the two independent growths of knowledge which are thus indicated. Probably no more weighty or influential calling exists for the industrial progress of the nation than that of the scientific engineers who are able to take into their view both sides of this field, and lead to the fertilization of each by the results of the other.

The progress of the science of heat forms one of the most interesting chapters in scientific history, and illustrates in a remarkable manner the way in which conceptions that at the time of their development appear of the most advanced and recondite character become the common elementary ideas of succeeding generations. The first great advance was no doubt the introduction of precision into the measurement of temperature by the invention of thermometers, and of the method of graduating them by first marking the fixed points on their scales. As Dr. Gamgee has recently pointed out, in a paper read before the Cambridge Philosophical Society, the fixed points by means of which Fahrenheit graduated his original alcohol thermometers were hardly physical at all; the higher one was the temperature of the armpit or mouth of a healthy man, which he had observed to be constant. It was after the Fahrenheit scale had been fixed by this temperature and that of the best available frigorific solution (snow and salt) that the construction for the first time of a mercury thermometer gave an opportunity of testing the boiling-point of water, which in this way was found to be constant, and under standard conditions to be at the point marked 212° on the scale. It was not until near our own time that the possession of methods of thermometry, combined with the researches of Black and others on the transfer and latency of heat, led, under the influence of Davy, Mayer, and Joule (and also Carnot), to the recognition of heat as a form of energy, and made possible an exact study of its transformations.

The final stage in the dynamical specification of the subject arrived when the very remarkable generalization of Carnot led, in Sir W. Thomson's hands, to a purely physical definition of a temperature scale, and the experiments of Joule and Thomson established the very close approximation of this scale to that of an ordinary thermometer, formed with one of the more permanent gases as expanding substance. This temperature scale enters into the general entropy equation employed by Clausius to express mathematically the results of Carnot's principle; so that in this form temperature has virtually a definition in analytical dynamics, and is an essential element in any dynamical theory which attempts to explain the phenomena of heat-transformation. These topics, treated in the simpler cases, now form a part of every course of physics.

The entropy formula expresses a relation between the initial and final states of the system, which is independent of the path of transition from the one to the other, provided this path be reversible. It is, therefore, to be classified with the fundamental dynamical investigations of Sir W. Rowan Hamilton, whose principal function is expressed in terms of the initial and final positions of the system, and the energy contained in it. It thus becomes a question of pure dynamics to inquire whether the entropy relation may be postulated as a general property of all motions, or whether its truth is constituted by the process of averaging the motions which is found essential to the development of the dynamical theory in the cases now in part unravelled, as, for instance, the kinetic theory of gases. In these discussions the chief difficulty is the dynamical realization and interpretation of temperature, as it is defined by its occurrence in the equation of entropy.

The nature of the difficulty is more fully realized when the fact is recognized that in a dynamical system, involving no dissipation of its energy to other systems, an exact reversal of the motions of all its molecular parts would cause it to retrace its original path, and would therefore reverse any degradation of energy in the thermodynamic sense that may have occurred in it. Thus, not merely is it possible for the thermodynamic order of Nature to be reversed by a continuous expenditure of intelligence without expenditure of energy, as in the case of the demons introduced by Clerk Maxwell into the exposition of the theory of gases; but a system may actually be put into such an initial state that it will go on reversing the laws of entropy of its own accord.

It is true that we are saved from the necessity of having to admit that such exceptions to the course of Nature may be actually existent; for all transfers of heat are inextricably mixed up with the phenomena of radiation, which involve transport of energy through the ether with a velocity the same as that of light, and which, therefore, require that if our system is to be absolutely conservative it must include the ether and extend beyond the farthest star. In any portion of a system thus constituted, however we may suppose degradation staved off and reversed by a complete reversal of its motions, the effect produced will be only temporary, and degradation will ultimately reassert itself.

Nevertheless, the problem remains for solution, how far the law of entropy, whose truth in a limited range is demonstrated by the fact that it is fundamental to the wide and firmly established science of thermodynamics, is to be considered as a principle of a purely dynamical character; and although the investigations of Clausius, von Helmholtz, Boltzmann, J. J. Thomson, and other mathematicians who have attacked the subject, have thrown much light on its affinities to known analytical laws of pure dynamics applied to systems in a steady state of motion, yet it is not too much to hope that there is a great deal more to be gained in this department of investigation.

In particular, a theoretical basis has yet to be supplied to the applications of the law of entropy to purely chemical actions. The results of its application to voltaic phenomena by Willard Gibbs and von Helmholtz have met with satisfactory experimental confirmation; while its extension to the theory of osmotic phenomena, dissociation, and the whole field of the chemical action of dilute solutions seems to be at any rate in qualitative accordance with facts, and even promises to fundamentally modify some of our notions of chemical action.

And there yet remains for answer the question which has long been put, whether there is any reason to suppose that the activities of living animal (or plant) tissue are limited by the principle in the same way as are those of dead matter.

The fundamental character of the views opened up by the development of Carnot's ideas on the efficiency of heat-engines adds a strong theoretical interest to the manner in which engineering practice has approximated to its ideal conclusions. Even though their full and complete application in the domain of heat-engines would not be questioned by anyone, yet it is clear that the investigations that have arisen out of their experimental testing and improvement have much value as illustrations and models for similar inquiries in more abstract departments of physics. Indeed, the subsidiary discussions in this treatise, relating to causes of waste of available energy, remind one, on a magnified scale, of the corresponding corrections necessary in thermo-chemical investigations, particularly those relating to entropy; and there seems to be a considerable field in which the one subject may profit from a study of the other. In this connection the admirable arrangement, discussion, and analysis contained in the chapters on the causes of loss of efficiency supply a store of information and general principles that would not otherwise be easily available for non-professional workers.

It is unfortunate that the science of thermodynamics suffers more than any other department of physics from the difficulty of exact comparison between theory and experiment. It may be a surprise to some people to learn that even the value of the mechanical equivalent of heat is hardly certain within 1 per cent.: it appears that recent experiments by Rowland give a result nearer to 782, that derived by Joule from the electrical method, than to 772, the value finally put forward by him from the results of several concordant series of direct experiments.

The treatise which has suggested these remarks contains a connected account of the different ways in which thermodynamic theory has been applied and realized, the subjects treated and co-ordinated ranging over air-engines, gas-engines, guns or powder-engines, reversed air-engines or refrigerators, and, in greatest detail of course, the different types of steam-engine. The reader will find in it a simplicity in the statement of physical results, and a freedom from the encumbrances of algebraic analysis in the discussion of general laws, which form one of the highest merits of a treatise on the principles of natural philosophy, and the most fitting preliminary to the examination by mathematical analysis of special problems. This is combined with a very interesting account, illustrated by actual examples derived from recent practice, of progress made in actual construction towards the ideal of perfection, which it would be beyond our province to refer to in detail. From the point of view of the student of physics, the book forms a most valuable supplement and corrective to the necessarily abstract discussions which form the substance of treatises on theoretical thermodynamics.

J. Larmor.

THE CLASSIFICATION OF ANIMALS.

Zoological Types and Classification. By W. E. Fothergill, M.A., B.Sc. (Edinburgh: James Thin, 1890.)

A Zoological Pocket-book or Synopsis of Animal Classification. By Emil Selenka and J. R. A. Davis, B.A. (London: C. Griffin and Co., 1890.)

THE author of the work bearing the first of the above titles has set himself a most formidable and ambitious task, viz. that of compressing into a small volume of 214 pages diagnoses of the organology of all classes and orders of living animals, together with brief descriptions of the structure of types of the latter, especially where represented by familiar creatures, and of adding thereto a list of most of the leading families, with short diagnoses of the same when occasion should demand. Such a book to be of real service should be as free of errors as possible; and, in view of the unprecedentedly rapid growth of zoological literature within the last two decades, the difficulties of the undertaking might be expected to be inversely proportionate to the smallness of the volume. The author sets out with the Protozoa, and advances, in ascending order, to the Primates. The plan of his work is a good one. Each fasciculus leads off (with few exceptions) with a recapitulation of the characters distinctive of the class with which it deals, and then follows a brief description of some central representative of each of its leading orders, and, in many instances, a tabular *résumé*. The book concludes with some notes upon the maturation and segmentation of the ovum. In dealing with the vertebrate vascular system, the author resorts to the construction of remarkable schemes which he believes may "aid the formation of a mental picture"; they appear to us to very efficiently confuse the mind, and we urgently recommend that their place be taken by diagrams which shall delineate the vessels themselves. The book, regarded as a piece of clerical work, is a good one, and the author has taken immense pains in compiling it. Its utility is, however, seriously marred by the constant recurrence of small errors, with which, as with insufficiently guarded assertions, it teems throughout. The mischief wrought by such, as distinguished from gross errors, which the student is tolerably certain to detect and rectify for himself, is, as the working of a subtle poison, slow but sure, and they cannot be too strenuously guarded against in an elementary treatise. Omissions, and occasional wrongly constructed sentences occur, and there is evident in places a want of uniformity of treatment—as, for example, the summary dismissal of the Echinodermata, and the non-recognition of the families of the important order Insectivora. Important groups, such as the Choano-flagellate Infusoria, and important characters, such as those of the central capsule of the Radiolaria and of the dentition of the Marmosets, pass unnoticed; while absolutely erroneous definitions are given of leading organs, such as the brain of the Craniata and the Arthropod eye—to say nothing of the relegation of the Arachnida and Prototracheata to the class Tracheata. There undoubtedly exists a demand for a book such as this which shall be up to date; and if the author will carefully revise his work this demand will have been met. The volume should serve as one of reference for the elementary student, and to this end it should be provided with an efficient index.

Under the second of the above titles there is in circulation a small volume of 238 pages, which is for the most part a translation of the third German edition of some notes printed for special use in Prof. Selenka's classes. They were originally intended "to serve for the reception of sketches and notes during lectures and practical work, and at the same time to facilitate a review of classification"; as reproduced in English, they are extensively interleaved, the blank paper being provided "to receive brief synopses from voluminous lecture notes" (*sic!*), "or, in some cases, definitions of families and smaller subdivisions." Numerous "additions and revisions" have been made by the translator, chief among them being a concise and well-compiled appendix of five to six pages, with a table, dealing with certain principles of distribution. This is, in some respects, the most satisfactory portion of the work, although in itself a literary essay such as might be produced by any intelligent student who had mastered the broad principles of his subject and could command scissors and paste. On turning to the body of the volume, we read, among other things, the following:—*Fierasfer* is parasitic upon Holothuria, *Exocoetus* is a Malacopteroid, *Diprotodon* was a springing Marsupial, *Glyptodon* was insectivorous. The *Rodentia* are diagnosed as deciduate Placentalia, with "$\frac{1}{1}$ chisel-shaped continuously growing incisors, and three to six back teeth with transverse folds of enamel"; while of the Apes it is said that the alisphenoids are "united with the parietals" (*Platyrrhini*) or are not united with them (*Catarrhini*), no mention being made of the malar. A novel version this of the discovery of Joseph and Forbes.

Upon the strength of his "additions and revisions" the translator practically claims a joint authorship. It will, we believe, be generally admitted that of all translations of the kind before us there are none which excel those into French. We have no wish to force comparisons, but we cannot refrain from contrasting the translator's work and assumed position towards Prof. Selenka's little volume, with, say, that of Carl Vogt towards Gegenbaur's "Grundzüge" or of Moquin-Tandon towards Claus's "Handbuch," the two finest translations of zoological treatises the world has yet seen. So efficiently has the translator of the last-named supplemented and extended the original that the French edition has become a new work; but, this notwithstanding, the translator is content to be regarded as such, and such alone. The endeavour, on the part of a translator or of an adapter, to pose as joint author of a work in connection with which he has performed a mere clerical labour is no new device; but it is one which cannot be too strongly denounced. It betokens, to say the least, an unfairness on the part of the junior which, it would not be difficult to show, has, in the past, amounted to an imposition upon the generosity of the senior, and to the infliction of a pang whose effects have been ineradicable. The translator of the work before us would have done well if, instead of having endeavoured to extend its scope, he had verified the accuracy of the statements which it contains. Why he should not have corrected errors such as those we have cited we are at a loss to understand; and he certainly should have avoided the addition of fresh defects. These seriously mar the pages of a book which, if revised anew, might be useful to the student.

G. B. H.

OUR BOOK SHELF.

The Hand-book of Folk-Lore. By G. L. Gomme. (London: Published for the Folk-Lore Society by D. Nutt, 1890.)

THE energetic Folk-Lore Society has just issued a handbook for the guidance of collectors and workers on folk-lore. The preparation of the work was intrusted to Mr. G. L. Gomme, the Director of the Society, who, it will be remembered, has recently published a very suggestive book entitled, "The Village Community," and is the author of numerous papers on folk-lore. Mr. Gomme has been assisted in the preparation of the book by several members of the Folk-Lore Society. At the outset Mr. Gomme defines "What folk-lore is," and after some judicious remarks he states: "From what has been advanced it may be conceded that the definition of the science of folk-lore, as the Society will in future study it, may be taken as follows, '*the comparison and identification of the survivals of archaic beliefs, customs, and traditions in modern ages*.'" The subject is divided into four sections, each of which is further subdivided. The principal divisions are as follows:—(1) Superstitious belief and practice: including superstitions connected with natural objects, goblindom, witchcraft, leechcraft, magic, beliefs relating to future life, &c. (2) Traditional customs: festival customs, ceremonial customs, games, local customs. (3) Traditional narratives: nursery tales, *Märchen*, fables, creation, deluge, &c., myths, ballads and songs, place legends. (4) Folk sayings: nursery rhymes, riddles, proverbs, nicknames, place rhymes. For each division there is a short account of the scope of that especial branch of folk-lore treated in a comparative manner, illustrations being drawn from the most varied sources; by this means the reader is enabled to gain a comprehensive view of the subject; then follow a number of questions for the guidance of collectors. The plan of the book is much the same as that of the well-known "Anthropological Notes and Queries," and it does for those interested in folk-lore what that estimable little work has done for the traveller—it instructs him what to do and how to do it. The author appeals not only to those who have the opportunity or the inclination to mix with "folk" (or "the less advanced classes in cultured nations"), but also to those who prefer to or possibly only can work in the library, and valuable hints are given to the latter, and two specimen tabulation forms are inserted. It is to be hoped that the publication of this carefully prepared hand-book will give definiteness of aim to the numerous people who take an interest in all "relics of an unrecorded past," and who would gladly collect information if they knew what was worth recording, how to arrange their facts, and where to send them to. Such information this book supplies, and the cost, being only half-a-crown, places it within reach of all.

Physikalische Krystallographie. By Dr. M. Liebisch, o.ö. Professor der Mineralogie an der Universität Göttingen. (Leipzig: Veit and Co., 1891.)

THIS book furnishes another example of the profound learning and patient industry of the German man of science. Dr. Liebisch, who is well known as one of the editors of the *Neues Jahrbuch für Mineralogie, Geologie, und Palaeontologie*, has recorded in the large octavo volume (of 614 pages) lying before us, a mass of investigations and abstruse mathematical proofs and deductions dealing with the physical properties of crystals. The subject is treated throughout in such a way as to bring out clearly the interesting relations existing between the physical phenomena and the geometrical symmetry of crystalline substances.

With this end in view, the author treats consecutively of homogeneous deformations, of the nature and orientation of isothermal planes, of thermo-electricity, of magnetic induction, of dielectrical polarization, and of pyro- and piëzo-electricity in crystals. The last part of the work deals with the elastic properties of crystals and with the remarkable applications of the theory of the elasticity of crystals on the changes in double refraction produced by pressure, concluding with an account of the investigations on the elastic deformation of dielectrical crystals in the electrical field and the electro-optic phenomena observable in piëzo-electrical crystals.

Not the least valuable part of the book is the series of beautiful plates at the end of the volume, illustrating pyro-electrical phenomena and the phenomena of interference in doubly refractive crystals, the figures being prepared from photographs made by the author. Worthy of note is the fact that Dr. Liebisch has succeeded in photographing interference phenomena displayed in the monochromatic light of the sodium flame.

Valuable as the book is in its completeness and accuracy of information, there are few, we venture to think, who possess sufficient mental digestive power to assimilate its learned contents. Even the professed crystallographer will no doubt find within its pages some rather heavy reading.

Anleitung zur Darstellung chemischer Präparate: ein Leitfaden für den praktischen Unterricht in der anorganischen Chemie. By Dr. Hugo Erdmann. (Frankfurt-a-M.: Verlag von H. Bechhold, 1891.)

A CONSIDERABLE evil of the present system of education is that the variety of subjects which a student has to pursue is increased, while the time at his disposal is, in many cases, less than it used to be. And as the examination is the only criterion of his success, both students and teachers are anxious to exclude all work that has not an immediate bearing upon this final test. In the study of chemistry, this state of affairs is leading to the exclusion of some of the most important branches of the subject, because practical examinations are invariably of an analytical character. When a student takes up organic chemistry, he is generally set to make a few preparations, and so accustom himself to work with larger quantities than a gram or two. But, although such practice is just as valuable and necessary to the student of inorganic chemistry, he very rarely enjoys a similar privilege. Dr. Erdmann has endeavoured to supply this deficiency so far as a guide-book is concerned, and though in many cases his directions are rather meagre, he has put together an excellent series of instructions which refer to compounds of all the commoner elements. The word inorganic is not too literally interpreted, for we find that oxalic acid crystallized and dry, ethyl bromide, hydrocyanic acid, urea, thiophen, Prussian blue, and some acetates are included. The volume of 71 pages concludes with a few useful notes concerning apparatus and processes, and gives directions for obtaining streams of several of the commoner gases without the aid of heat.

Analysis of a Simple Salt. By William Briggs, F.C.S., and R. W. Stewart, B.Sc. Lond. (London: B. W. Clive and Co.)

IN compiling a guide, it is a good thing to go to the best sources for information, but it is a graceful thing to acknowledge whence the information has been gathered. We do not for a moment suggest that every paragraph should be encumbered with a statement of the various authorities that support the facts expressed in it; but when the manner and order of treatment, and very often the actual verbiage, are taken from a volume that is still in current use, it is certainly due to all who have an interest in that volume, that the compilers shall acknowledge their indebtedness. If the compilers had followed more closely still the scheme for the "preliminary examination in the dry way" as detailed in Valentin's "Qualitative Analysis," we think they would have improved their method. And it may also be remarked that, to prepare always neutral solutions in searching for acids, leads to much waste of time, and especially so when the substance for analysis is a simple salt. A few specimen analyses are added at the end of the book. These, even when judged of by the tables given in the body of the work, are not always complete, and sometimes inaccurate. Overlooking the points already referred to, the volume is likely to prove a useful and trustworthy assistance to those for whom it is especially intended.

Magnetism and Electricity. By J. Spencer, B.Sc. (Lond.), F.C.S. (London: Percival and Co., 1890.)

THIS work will form a useful class-book when the elementary parts of these subjects are being taught. It is divided into three parts, the first dealing with magnetism, while the other two treat of electricity, subdivided into frictional and voltaic electricity. The idea throughout has been to arrange a series of easy experiments, which the teacher or student can with little difficulty perform. In each case good instructions are given, and, following these, are the conclusions which can be derived from them. The scope of the subjects under treatment is limited to the elementary stage of the Science and Art Department, and at the conclusion of each chapter are arranged exercises, among which are some that have been previously set by that Department. In the appendix will be found the syllabus, and questions that have formed the subject of examinations of the Department during the last two years, which should be found useful to both teachers and students.

The Elements of Euclid. Books I. and II. By Horace Deighton, M.A. New Edition, Revised. (Cambridge: Deighton, Bell, and Co., 1891.)

THE chief alterations made in this new edition consist in the introduction of symbols and abbreviations; and in order that beginners should not be confused with them at the commencement, the first fifteen propositions are proved without their use, with the exception of the symbols for therefore, because, and equal to. For several of the exercises the author has substituted others which he considers more suitable, and, in addition, some new ones have been inserted. Of the two books dealt with, Book I. is treated very fully, and each proposition is followed by a considerable number of easy examples, which, if worked out by the student, should give him a thorough knowledge of the propositions preceding them. A most useful collection of propositions is added, with which the reader is recommended to make himself familiar.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. Wallace on Physiological Selection.

I WILL endeavour, as briefly as possible, to justify what I have said elsewhere touching "the peculiar position to which Mr. Wallace has eventually gravitated with reference to my views." For a fuller statement I must refer to the *Monist*, vol. i. pp. 1–20.

It is quite true, as he says, that "in his original paper, and in the summary of it published in NATURE, Dr. Romanes adduced variations in regard to fertility and sterility as the fundamental fact in physiological selection." And this is exactly what Mr. Wallace himself has done in his "alternative theory." Taking it for granted that these variations must always occur—as in my "original paper" I said they probably "most frequently" occur—in a whole race or strain, his theory seeks to explain, (1) the *causes* of such variations, and (2) their *effects* in furnishing an important condition to the origination of specific types, and this exactly in the manner that the theory of physiological selection had previously exhibited. Space forbids any long quotations, and therefore on the present occasion I will confine myself to transcribing two sentences from the paragraph in which he very correctly summarizes his theory, viz. the sentences which deal with the *effects* of these "variations in regard to fertility and sterility."

"The preceding argument, it will be seen, depends entirely upon the assumption that some amount of infertility characterizes the distinct varieties which are in process of differentiation into species. . . . It is by no means necessary that all varieties should exhibit incipient infertility, but only some varieties; for we know that, of the innumerable varieties that occur, but few become developed into distinct species; and it may be that the absence of infertility, to obviate the effects of intercrossing, is one of the usual causes of their failure."

Here we have the whole essence of "physiological selection" in a nutshell. The first sentence conveys the "fundamental fact;" the second indicates its possibly important consequence in permitting the origination of species by preventing the effects of intercrossing. Why, then, does Mr. Wallace not perceive that this is the whole essence of physiological selection? As far as I can understand, the reason appears to be that he deems his variations in the direction of cross-infertility to differ from mine, in that while his may be associated with other conditions or causes of modification, mine, as he now repeats in NATURE, are supposed always to act "alone in an otherwise undifferentiated species." Now, not only did I expressly guard against this interpretation in my "original paper," but in all my answers to Mr. Wallace's criticisms which have since appeared I have over and over again corrected the mis-statement on his part; and I am the more surprised that he should again reproduce it as the sole basis of his present reply, inasmuch as some of the passages which he quotes for this purpose from the paper in question themselves furnish the needful correction in their own immediate context.[1] Moreover, not only have I thus from the first fully recognized the sundry other causes of specific change with which the physiological variations may be associated; but Mr. Gulick has gone into this side of our common theory much more fully, and elaborately calculated out the high ratio in which the differentiating agency of any of these other causes must be increased when assisted by—*i.e.* associated with—even a moderate degree of the selective fertility, and *vice versâ*. Therefore, it is simply impossible for Mr. Wallace to show that "our theory" differs from his in this respect. Yet it is the only respect in which his reply alleges any difference.

I do indeed myself believe that in many cases the physiological variation may arise alone, in an otherwise undifferentiated species; but from the first I have always maintained that it makes no essential difference to the theory in what proportional number of cases it has done so. And in a forthcoming treatise I shall be able very completely to dispose of Mr. Wallace's "two carefully considered cases," whereby he claims to have proved that the possibility of physiological selection ever working alone is "absolutely unfounded."[2] At present, however, the point is that, even if I am wrong in supposing that physiological selection can ever act alone, the principle of physiological selection, as I have stated it, is not thereby affected. And this principle is, as Mr. Wallace has re-stated it, "that some amount of infertility characterizes the distinct varieties which are in process of differentiation into species"—infertility, whose absence, "to obviate the effects of intercrossing, may be one of the

[1] For instance, to take only the first of his "few quotations," he reproduces by itself the following sentence:—"It becomes almost impossible to doubt that the primary specific distinction [meaning sterility] is, as a general rule, the primordial distinction." Now this, be it remembered, is quoted for the expressed purpose of "making it absolutely clear that Dr. Romanes's theory of physiological selection, so far as it had any originality, *was founded on the supposition of sterility alone, arising in an otherwise undifferentiated species*." Yet, if Mr. Wallace had but read the context, he would have seen that this statement is directly contradicted. For the very next sentence is as follows:—"I say as a general rule, because the next point which I wish to present is, that it constitutes no part of my argument to deny that in some—possibly in many—cases *the primary distinction may have been superinduced by the secondary distinctions*." By the "primary distinction" Mr. Wallace correctly understands me to mean cross-infertility between allied species, while by "secondary distinctions" it is explained in the same place that I mean specific characters of all other kinds. The passage then goes on, through a number of pages, to show "how natural selection, or any other cause [which is concerned in the differentiation of species], may have induced this particular kind of variation in the reproductive system by its operations on other parts of the organism," and the ultimate conclusion of this lengthy argument is: "Thus, we see, it really makes no essential difference to my theory whether it be supposed, in any given case, that the primary distinction was prior, or subsequent to the secondary distinctions." Comment appears needless.

[2] These cases consist in some exceedingly simple arithmetical computations, which, as I shall hereafter show, rest upon erroneous data. Mr. Fletcher Moulton, who has kindly gone into the matter in a really efficient manner from the mathematical point of view, reports, to use his own words, "an enormous difference from Mr. Wallace's results."

usual causes of their failure to become developed into distinct species."

This, I repeat, is the essence of physiological selection; and any "originality" which my views upon the subject present consists in recognizing the "fundamental fact" set forth in the first of the two sentences above quoted, together with its consequence as set forth in the second. Before Mr. Catchpool published the theory in these columns, no one—with the partial exception of Mr. Belt—had perceived this factor of organic evolution; and while, for about the sixth time, repudiating the grotesque "originality" which Mr. Wallace continues to ascribe, I may conclude by observing that—personalities apart—it is to me a matter of satisfaction that he has now himself begun to perceive the existence and the importance of the factor in question.[1] George J. Romanes.

Oxford, December 1.

The Tornado.

In Nature, vol. xlii. p. 612, there appears a notice of my book on "The Tornado," from "H. F. B." I must thank so high an authority for noticing the book; all I ask for is a full, free, and fair discussion of the facts presented. May I call attention to one or two points which may not be clearly understood?

(1) My object in writing the book was to bring together all the facts known regarding tornadoes, and to give a brief *résumé* of theories, as far as possible, showing the gradual development during the past fifty years.

(2) I have nowhere touched one of Prof. Ferrel's mathematical discussions of the problem. In some cases I have tried to show that there may be an interpretation of certain physical phenomena not exactly in accord with his own views.

(3) I have not denied a single thermodynamic principle. The quotations given by "H. F. B." are quite plain when the book is read as a whole. These do not refer to thermodynamic principles at all, but rather to the experiments made by Prof. Espy nearly fifty years ago, and whose results I have tried myself to check. I am sure that anyone who carefully peruses the book will be satisfied that there have been read into it statements or inferences which are not there.

(4) Above all, I have not advanced any visionary electric speculations regarding the generation of tornadoes. Rather I have tried to avoid that very thing. In the very quotation made by "H. F. B.," from p. 76, occur these words:—"It has been my purpose for many years to avoid, as much as possible, all speculations in considering air motions and the causes of atmospheric phenomena. This is especially pertinent when we consider electric action in the atmosphere. It is very difficult to believe that electricity has nothing to do with our thunderstorms."

It is a significant fact that "H. F. B." begins his quotation with this last clause, and from it tries to show that I have adopted an electric hypothesis. I cannot quite see why he did not begin where he should have done. I have not given my name to any hypothesis at all, but have advanced a few facts which I hope may ultimately help us to build up the true view of tornadic phenomena.

The familiar lecture experiment of forming a cloud in a receiver by a stroke of the air-pump is given by "H. F. B." as an illustration of dynamic cooling. It would be quite interesting if some one would compute the amount of work done by the air in this case, premising that the stroke of the pump is made quickly enough to form a vacuum into which the air from the receiver rushes. Tyndall says: "Mere rarefaction is not of itself sufficient to produce a lowering of the mean temperature of a mass of air." It is quite well known that the work done in this experiment is not that of driving out a piston, but is rather the very slight work needed to impart a motion to the molecules in the receiver—in other words, to drive out these particles from the receiver.

As to whether a dense and cold stratum of air in motion can overrun a warmer stratum, I have to say that this question has been negatively settled in this country. While such a condition might be possible in quiescent air, and has been observed in balloon voyages, yet in these cases there was no disturbance of the atmospheric equilibrium. In balloon voyages I have myself found a distribution of temperature in a vertical direction, which, according to theory, should have given rise to a violent tornado, but there was no marked disturbance. I have faith to believe that in the near future there is to be a marshalling of facts which shall establish true views of storm-generation; and even now there are many intelligent men who have grown restive under the present pure theories and mathematical analyses of atmospheric phenomena. To my mind, the Dr. Hann agitation has done a great deal to open the eyes of orthodox meteorologists, and even "H. F. B." seems to be in a little doubt as to the final outcome of his views in relation to orthodox meteorology. It seems to me all persons who are studying storm-generation and movements are realizing the absolute need of a solid ground-work of fact on which to base our views, and this is the great point that I have been contending for these many years.

Washington, D.C., November 18. H. A. Hazen.

Prof. Hazen can alone speak as to what views he intended to advocate; a reviewer can only take count of such as are expressed or implied in the work he reviews, and the present writer is unable to see in the above letter any evidence that the quotations given from Prof. Hazen's work were not fairly representative of his text, or that they fail to justify the comments upon them. That he is not alone in his inference that Prof. Hazen "appears to regard as inapplicable to the movements of the atmosphere, those laws of thermodynamics that are based on the results of Joule's labours," is shown in the following extract from Prof. J. Hann's paper in the September number of the *Meteorologische Zeitschrift*:—"Da Herr Hazen so ziemlich alle Grundlagen, auf welchen man die Meteorologie in neuerer Zeit mit Sicherheit weiter ausbauen zu können vermeint, leugnet oder in Zweifel zieht, darunter selbst allgemein anerkannte physikalische Gesetze, wie. z. B. die adiabatische Temperatur-Aenderungen in feuchter Luft, so scheint es zunächst allerdings überflüssig, sich mit ihm in eine Kontroverse einzulassen, da der Boden für eine Verständigung gänzlich fehlt." The passage referred to in this remark is one of those quoted in the present writer's review.

H. F. B.

Araucaria Cones.

I am drawn to add, with your permission, a few words to what has already been written on the subject of Araucaria cones, by noticing that all your correspondents speak of trees situated in the south of the British Isles, or, at least, not further north than Cambridge, whereas it may be of equal, if not greater, interest to the Duke of Argyll and others to know something of the behaviour of the Araucaria in the north of Scotland. It also seems to me unfortunate that many of the correspondents have omitted to mention the most interesting point concerning the fruiting of the Araucaria, viz. the monœcious or diœcious character of the trees they describe. Loudon, in his well-known book on the "Trees and Shrubs of Great Britain," pronounces the Araucaria to be diœcious. At that time knowledge could only be gained of it on its native hills. In the "Manual of Coniferæ," published by J. Veitch and Sons, is figured a branch from the monœcious tree at Bicton with both pollen and ovule-bearing catkins. It would be interesting to learn if many of the

[1] It is, perhaps, desirable to add, as already stated elsewhere, that I entertain no doubt at all touching the unconscious or unintentional nature of the "adoption." Nevertheless, I may further add, the adoption itself is so manifest, that several eminent men of science wrote to me on the subject when first his work on "Darwinism" appeared. Among the mildest of their comments are:—"Mr. Wallace has treated you very badly. After having set up a caricature of your theory, he adopts the theory itself, pure and simple." But of more importance is Mr. Gulick's opinion, seeing that he was the first to conceive, though the last to publish, the theory of physiological selection. As soon as he had read "Darwinism," he wrote me from Japan a long letter, the substance of which may be gathered from the first two sentences, as follows.—"Mr. Wallace has most certainly adopted the fundamental principles of our theory. He takes our principles, which in the previous chapter he has combated: but he makes such disjointed use of them that I am not willing to recognize his statement as an intelligible exposition of our theory." More recently he sent to the *American Journal of Science* a paper, which he summarizes thus:—"Mr. Wallace's criticism of the theory of physiological selection is unsatisfactory: (1) because he accepts the fundamental principles of that theory on pp. 173–79, in that he maintains that without the cross-infertility the incipient species there considered would be swamped; (2) because he assumes that physiological selection pertains simply to the infertility of first crosses, and has nothing to do with the infertility of mongrels or hybrids; (3) because he assumes that infertility between first crosses is of rare occurrence between species of the same genus, ignoring the fact that, in many species of plants, the pollen of the species is prepotent on the stigma of the same species when it has to compete with the pollen of other species of the same genus; (4) because he not only ignores Mr. Romanes' statement that cross-infertility often affects 'a whole race or strain,' but gratuitously assumes that the theory of physiological selection excludes this 'racial incompatibility' (which Mr. Romanes maintains is the 'more probable form'), and bases his computation on the assumption that the cross-infertility cannot be associated with any other form of segregation.

trees now under cultivation are monœcious, the tree perhaps adapting itself to the enforced solitude of its new abode in gardens. However, it appears at present to be both monœcious and diœcious, like several other Coniferæ.

In the grounds at Beaufort Castle, near Inverness, are several specimens of this Araucaria, producing only male or pollen-bearing catkins. One, a particularly fine tree, has borne such pendent cones for several years past. Last week I had the opportunity of inspecting a rather famous Araucaria at Conan, the seat of Sir Kenneth Mackenzie. This is said to be one of the first three specimens introduced into Scotland; the other two at Edinburgh were, I believe, killed by the severe winter of 1860. The tree at Conan has lost all its lower branches, and has grown but little of late years; it, however, yearly produces the erect ovule-bearing cones, and about twelve years ago, these contained fertile seed. Specimens grown from the seed of that year are still thriving at Gairloch, on the north-west coast of Scotland. No fertile seeds have been produced since; and as there was no other specimen certainly within several miles that could have produced the necessary pollen, we must conclude in the absence of direct evidence that this is a diœcious tree, and produced the more insignificant male catkins on the one occasion only. I therefore need hardly point out that unless the Araucaria at Inveraray is also provided with male flowers, or some other specimen similarly provided grows in the neighbourhood, the Duke of Argyll may assuredly expect his lawn to be strewn next year with only empty seed-vessels.

In answer to Mr. Gardiner, I may remark that I could detect no difference in habit or foliage between the diœcious male tree at Beaufort and the monœcious one at Conan; the latter, however, is so much damaged as to render comparison difficult.

ADRIAN WELD-BLUNDELL.

The Abbey, Fort Augustus, November 30.

YOUR correspondent, Mr. A. D. Webster, in your issue of November 20 (p. 57), states that the male catkins of the above tree are extremely rare as compared with the fruiting cones. If this is the case, though my own observations would have led me to the contrary opinion—the following instances may be of interest. I have observed the male catkins on a tree in the cemetery of this town for two or three successive years, in considerable quantities. In the grounds at The Elms, Houghton, Hunts., there is a tree which for several years past has borne large quantities of the male "amenta," giving to it, as your correspondent describes, a very striking appearance. Another tree in the same grounds has this year produced a single specimen of the same nature, while a third, of the opposite sex, is also developing a fruiting cone, which will doubtless, in the near proximity of the pollen-bearing ones, perfect its seeds.

Among specimens of the male catkins that I possess from the latter place is one which is "double," the floral axis being bifid. It has occurred to me that this may be some slight indication as to the much-vexed question of the morphology of the "amenta," whether each consists of a series of *monandrous* flowers or constitutes a single *polyandrous* one; the above monstrosity seeming to point towards the former, as the bifurcation of the axis of an *inflorescence* is a common phenomenon, that of a single *flower* being, on the contrary, much rarer.

I am not sure whether I should be right in generalizing from the comparatively few fruiting examples I have seen, but in the cases which have come under my observation the female trees have been more distantly branched than the male, where the ramification is considerably closer and more luxuriant.

Northampton, December 3. H. N. DIXON.

Dry-rot Fungus.

THE "beautiful growth of fungus covering the wall and floor (in a wine-cellar) to a depth of 4 inches, suggesting cotton-wool in form and colour," referred to by "M. H. M.," is the destructive dry-rot (*Merulius lacrymans*), and I would advise your correspondent to make war upon it without delay. The cotton-wool form is an early stage of the fungus. If neglected, it will in a few months develop a leathery sheet, sending out tough leathery cords a quarter of an inch thick, with spore-bearing folds of a rusty colour. These spores will scatter themselves all over the cellar, and will be difficult to eradicate. The mycelium of the fungus buries itself in any kind of wood, especially deal, runs rapidly down the longitudinal fibres, and, as it goes, destroys the "nature" of the wood, so that it snaps and crumbles under the slightest pressure. I have had to deal with this pest in a range of cellars with a timber roof, and have found the best remedy to be repeated applications of corrosive sublimate dissolved in methylated spirit freely painted on the timber, walls, or floor, wherever the "cotton-wool" makes its appearance. I had to cut away 8 feet in length of a 10-inch Memel beam which was permeated by the mycelium, and rotten to the core. Between the end of this beam and the back of the recess in the brick wall in which it rested was a vacant space filled with the mature fungus full of spores. This was two years ago. I have been fighting the fungus ever since with the corrosive sublimate, and have nearly exterminated it. The first appearance of the cotton-wool should be attacked without delay. F. T. MOTT.

Birstal Hill, Leicester.

The Effect of Fog on Plants.

As my name appears somewhat prominently in your note on the important inquiry into the effect of fog on plants, may I explain that the experimental investigation of the subject from a botanical point of view is entirely in the able hands of my friend, Dr. Oliver?

I am prepared, as stated in the Scientific Committee's circular, to examine any specimens of plants affected by fog which may be sent to me, but my share in the work does not go beyond this.

The inquiry is of very great interest, both to horticulturalists and botanists, and I am glad that it has been noticed in the columns of NATURE. D. H. SCOTT.

Royal College of Science, South Kensington,
London, S.W., December 6.

Great Waterfalls.

WOULD you allow me to supplement my inquiries published in last week's NATURE (p. 105) by asking for a description of the Pambam-arivy Falls in India, of which I have only the following brief note:—"In the Travancore Hills between Tinevelly and Travancore is situate the magnificent Pambam-arivy, or Snake Fall. It is a double fall, descending in the first plunge from the cliff edge 1200 feet, and it can be seen from a distance of forty miles." ARTHUR G. GUILLEMARD.

Eltham, Kent, December 9.

A Band of Light.

THE account of the so-called comet that was seen by Mr. Eddie at Grahamstown (see NATURE, November 27, p. 89) reminds me of the phenomenon seen some years ago in this country during an auroral display. A band of light, in shape somewhat resembling a comet, was seen to move across the sky, rising in the north-east and disappearing in the north-west; it moved, however, much faster than the comet-like body lately observed, being in sight, as far as I remember, only one or two minutes. C. C.

Trinity College, Cambridge.

Some Habits of the Spider.

THE following record of the habit of certain spiders, alluded to by "A. S. E.," is the only one known to me. "He saw great spiders with crowns and crosses marked on their backs, who sat in the middle of their webs, and when they saw you coming, shook them so fast that they became invisible" (Kingsley, "Water Babies," p. 40.) W. E. H.

BOTANICAL ENTERPRISE IN THE WEST INDIES.

DURING the last twelve years considerable effort has been made to enlarge the sphere of action of the botanical organizations in the West Indies. At the beginning of the period there were only two botanical establishments in this part of the world, one at Jamaica and the other at Trinidad. Since that time an important botanical garden has been successfully established at British Guiana, and lately a scheme of botanical stations has been put forth to suit the circumstances of the smaller islands, described in these columns (vol. xxxv. pp. 248-250). This scheme of botanical stations for the West Indies has been very carefully and assiduously fostered at Kew, and it appears now as if it were likely to be fully carried out. It was felt that the smaller islands under present circumstances could not support any considerable organization of their own, but, on the other hand, if they joined together and affiliated their stations to one or other of the larger gardens there were good grounds for believing that satisfactory results would be attained.

Stations have been already established at Grenada, St. Vincent, St Lucia, Barbados, and Antigua, while others are in course of being established at Dominica, and St. Kitts, and Nevis. The curators of these stations are carefully trained men (mostly from Kew), whose chief qualification is a thorough knowledge of horticultural methods as applied to tropical plants. They devote themselves to the maintenance of the stations as centres for the growth and distribution of economic plants, and they carry on experiments with the view of improving old or introducing new industries. It may readily be gathered that the objects of these stations are thus of a very simple and unassuming character. They necessarily work within narrow limits. They cannot give much attention to plants of a purely decorative character, or, again, to the maintenance of large areas under cultivation as pleasure grounds. The main object in view is to meet the special circumstances of the West Indies at the present time, and do all that is possible to encourage a diversified system of cultural industries so that they may not suffer so much as hitherto from fluctuations of prices in the chief staples.

It is believed that the Botanical station scheme will eventually meet the wants of each island in a simple and economical manner. It will become the basis of a federation for purely economic purposes likely to be generally beneficial both to the European planter and the Negro small proprietor. The stations will, it is hoped, have the occasional supervision of the heads of the Botanical Departments at Jamaica and Trinidad, and they will draw from thence such supplies of seeds and plants as may be required from time to time for their special wants.

In the organization of the scheme successive Secretaries of State for the Colonies have taken a warm interest, while the elaboration of the details has necessarily to a large extent fallen upon Kew. As the scheme took root, the discussion of these details involved a rather heavy burden of correspondence. It was eventually felt to be advisable both by the West Indian Governments immediately concerned and by the Colonial Office, that one of the Kew Staff should proceed to the West Indies in order to advise on the spot as to the various questions incidental to the successful start of the various stations. The mission was accordingly intrusted to the Assistant-Director, Mr. Morris, who has had a considerable experience of planting industries both in the Old World and in the New. Mr. Morris left by the mail of November 12, and will be absent about three months.

NOTES.

MR. W. F. R. WELDON, F.R.S., has been appointed by the Council of University College, London, to the Jodrell Professorship of Comparative Anatomy and Zoology, which was held for sixteen years by Prof. Ray Lankester. Mr. Weldon is a Fellow of St. John's College, Cambridge, and is a lecturer on Invertebrate Morphology to the University of Cambridge.

THE Council of the Royal Geographical Society has agreed to grant £200 to Mr. Theodore Bent to aid him in exploring the now famous ruins in Mashonaland.

ACCORDING to the *Colonies and India*, the important post of Superintendent-General of Education in the Cape Colony will fall vacant at the end of the present year, owing to the retirement, after 30 years' service, of Sir Langham Dale, K.C.M.G. This gentleman was in 1848 selected by Sir John Herschel to be Professor of Classics in the South African College, Cape Town, and in 1859 was appointed to the office which he now holds. He also became Vice-Chancellor of the University of the Cape of Good Hope in 1873. The value of the appointment is £1000 per annum.

THE Whitworth Trustees have added to their gifts to Manchester 12½ acres of land, known as the Stanley Grove Estate, purchased by them for £27,000, for a hospital under the direction of the Owens College. The site is alongside the Whitworth Park.

ACCORDING to the will of the late Sir Edwin Chadwick, a trust fund is to be applied as the trustees shall direct for the advancement of sanitary science. By a codicil to his will, the testator suggests that the trustees may offer a cup of the value of £20 to be given annually, for a term of years, to sanitary authorities at home or abroad showing the greatest reduction in the death-rate of the population in their district. He suggests also the offer of a silver medal to the school teacher showing the best mental results of the half-time principle, and a gold medal for district school managers obtaining the best results in subjects named.

LAST week we referred, in a leading article, to a Conference convened by the National Association for the Promotion of Technical and Secondary Education for the purpose of considering the best means of utilizing the new fund placed at the disposal of County Councils under the Local Taxation Act of this year for the promotion of education. The Conference met on Friday, December 5, and was largely attended. Lord Hartington, who occupied the chair, opened the proceedings with a short speech, in which he urged that the best way of securing the fund will be to see that it is used for the purpose for which it was originally granted, by stimulating existing institutions in the work they are now doing, by adding a scientific and practical side to schools, and providing new schools where such do not now exist. There are, he pointed out, many ways in which the grant can be applied, and it is clear that one cut-and-dried system cannot be applied throughout the country. The system in urban districts must be different from that established in agricultural districts. The secretaries presented a report on the working of the Technical Instruction Act and the Local Taxation Act; and afterwards there was a most careful discussion of all aspects of the question which the Conference had met to consider. No formal motions were adopted, as several members of the Conference felt that they could not commit their County Councils to definite resolutions. In the course of the discussion Sir W. Hart Dyke assured the Association of his willingness in every possible way to co-operate with them. Mr. Mundella said the best result of the meeting would be if it insured the continuance of the grant in the channel in which they wished it to go. If this money was not promptly utilized for education, it might revert to the Treasury. No doubt embarrassment might be felt in some localities, but he would recommend in such case that the money should be placed in a suspense account, which the Act enabled them to do. The total absence of provision for intermediate education had been a grave defect in our system. Wales had appropriated the whole fund, and stood higher in respect of intermediate education than any other part of the country.

THE Second International Ornithological Congress will be held at Buda-Pesth in May 1891. The Hungarian Committee invite all specialists and members of Ornithological Societies to attend the meeting. There will be excursions to various parts of Hungary of ornithological interest. An official programme will shortly be published.

AT a meeting of the State Commissioners on Niagara Falls, held at New York on December 8, a report was presented from the State Engineer upon the survey which has just been made. According to a telegram sent through Dalziel's Agency, this report gives particulars of the recession of the Falls since 1742, when the first survey was made. It shows that the total mean recession of the Horse-Shoe Falls since 1742 has been 104 feet 6 inches. The maximum recession at one point is 270 feet. The mean recession of the American Falls is 30 feet 6 inches. The length of the crest has increased from 2260 to 3010 feet by the washing away of the embankment. The total area of recession of the American Falls is 32,900 square feet, and that of the Horse-Shoe Falls 275,400 feet.

DR. BERGHAUS, the well-known geographer, died at Gotha on December 3.

THE death is announced at Warsaw of Herr Anton Waga, one of the most eminent Polish naturalists, at the age of 91.

MR. R. D. OLDHAM, of the Geological Survey of India, has been attached to the military expedition into the Zhob country. His principal duty will be to inquire into the reported oil-fields in the Shirani country. The last specimen examined by an expert has been declared of most excellent quality.

A DESPATCH from Mexico states that an earthquake, lasting some minutes, occurred there on the evening of December 2. The shock was the severest felt for years, and the inhabitants rushed into the streets in terror.

EXTENSIVE subsidences of cliff have taken place at Walton-on-Naze, Essex. In one spot a surface area of 100 square feet slid bodily down to the beach, carrying with it part of a road leading to Frinton. Opposite the Marine Hotel, Walton, where the cliff is lower, a chasm large enough to berth a Thames steamboat has opened in the sea-front. The *Times* says that landslips have resulted from the loosening of the soil of the cliff through the action of springs, rather than from the direct attack of the sea.

THE Decimal Association has issued a pamphlet containing a popular explanation of decimal coinage, weights, and measures, by Sir Guilford Molesworth and Mr. J. Emerson Dawson. The information is condensed as much as possible under different headings, all examples and evidence in support of the statements put forward being relegated to appendices.

AT the meeting of the American National Academy of Sciences at Boston on November 11, 12, and 13, the following papers were presented:—On the primary cleavage products formed in the digestion of the albuminoid, gelatine, by R. H. Chittenden; on the classification and distribution of stellar spectra, by Edward C. Pickering; on the relation of atmospheric electricity, magnetic storms and weather elements, to a case of traumatic neuralgia, by R. Catlin; on the growth of children studied by Galton's method of percentile grades, by Henry P. Bowditch; on electrical oscillations in air, together with spectroscopic study of the motions of molecules in electrical discharges, by John Trowbridge; some considerations regarding Helmholtz's theory of dissonance, by Charles R. Cross; a critical study of a combined metre and yard upon a surface of gold, the metre having subdivisions to two millimetres, and the yard to tenths of inches, by W. A. Rogers; on evaporation as a disturbing element in the determination of temperatures, by W. A. Rogers; on the use of the phonograph in the study of the languages of the American Indians, by J. Walter Fewkes; on the probable loss in the enumeration of the coloured people of the United States, at the census of 1870, by Francis A. Walker; on the capture of periodic comets by Jupiter, by H. A. Newton; on the proteids of the oat-kernel, by Thomas B. Osborne; on the present aspect of the problems concerning Lexell's comet, by S. C. Chandler; the Great Falls coal-field, Montana, its geological age and relations, by J. S Newberry; notes on the separation of the oxides in cerite, samarskite, and gadolinite, by Wolcott Gibbs; on the relationships of the Cyclopteroidea, by Theo. Gill; on the origin of electro-magnetic waves, by Amos E. Dolbear.

A PAPER by Mr. W. B. Mason in the Transactions of the Seismological Society of Japan deserves the attention of all who take special interest in seismology. It contains a list of earthquakes recorded at telegraph stations in central and northern Japan from August 11, 1888, to December 31, 1889. Mr. Mason, while allowing for various sources of uncertainty in the observations, thinks that some results may be deduced from what are still meagre statistics. Thus of the 151 earthquakes recorded in Tokio only 89 were felt at the other telegraph stations. Some of those which were felt at all the stations seem to have been felt at almost exactly the same instant. In other words, there was no indication of a progression of the earthquake from point to point.

THE Brooklyn Institute is making most praiseworthy efforts to raise the standard of geographical teaching in the United States. Through its Department of Geography it will open, about the new year, an exhibition of specimens of the best geographical text-books, maps, atlases, globes, reliefs, models, telluria, and other apparatus used in the various countries of Europe and America in their courses of gergraphical instruction. The collection will be exhibited first in the building of the Brooklyn Institute, then in New York, Philadelphia, Boston, Baltimore, Washington, Chicago, St. Louis, and other great centres of population. The entire collection, with the exception of specimens which have been lent, will afterwards be arranged as a permanent exhibition in the building of the Brooklyn Institute. *Science*, from which we learn these details, says that, in connection with the exhibition, the Brooklyn Institute is collecting material for a comprehensive report which it will publish regarding the position and methods of geographical instruction in America and Europe.

THE Chief Signal Officer of the United States has just issued his Report for the year ending June 30, 1890. It shows that the meteorological department is yearly increasing in extent and importance; the duties include the issue of forecasts and storm warnings, the gauging of rivers for navigation and flood-warnings, the reporting of temperature and rainfall conditions for the cotton interests, the display of frost-warnings in the interest of agriculture, and the notification of advancing cold waves for the benefit of the general public. The average percentage of successful weather forecasts amounted to 82·6. Long time forecasts are also issued at the discretion of the forecast official, with successful percentages of 81·6 for 48 hours, and 80·5 for 72 hours. The demands for daily weather charts have increased to a remarkable extent; the subscription for them is two cents. a copy. The co-operation with the Meteorological Office in Paris is continued; each night a cablegram is sent to the latter office summarizing the synchronous meteorological observations, gales, derelicts and dangerous ice of the western Atlantic for the previous five days, together with the current weather conditions of the United States. Part of this information is regularly published in the Paris *Bulletin International*. The Report states that a card index of the stations in the United States at which meteorological observations have ever been taken is being prepared; when finished, it will afford a comprehensive history of the climatic observations in that country. Various important scientific researches are being carried on, among them the accurate determination of the velocity of the wind, and more particularly its actual pressure during violent gusts, by Prof. Marvin; the relation of the dewpoint to the subsequent movement of the storm-centre, by Captain Allen; and the determination of the average destruction caused by tornadoes, by Prof. Hazen. The average number of persons killed by them is 102 yearly—which is considerably less than the number killed by lightning. These reports will be eventually printed as appendices to the General Report.

AT the meeting of the Linnean Society of New South Wales on October 29, Mr. J. J. Fletcher read a paper presenting contributions to a more exact knowledge of the geographical distribution of Australian Batrachia. While the broad facts relating to the geographical distribution of Australian Batrachia are fairly well known, much yet remains to be learnt respecting details, especially in regard to inland forms, since the species were originally described chiefly as they came to hand and without reference to the general batrachian fauna of the particular localities from which the types came, and with very few exceptions from coastal habitats. In Mr. Fletcher's paper, the first of what promises to be a useful series, three fairly complete collections are recorded from Dunoon, Richmond River (12 species); Guntawang, near Mudgee (13 species); and Dandaloo, Bogan River (10 species); and comparisons are instituted between the Batrachia of these localities and those of Port Jackson, the Blue Mountains, and Illawarra.

IN the report on the Chillingham cattle, read at the British Association in 1887, the following statement is made: "The cattle live on good terms with the red-deer, but they will not tolerate fallow-deer or sheep in the park." With regard to this statement, Mr. C. Oldham, of Ashton-on-Mersey, says in the December number of the *Zoologist* that on September 13 last, when at Chillingham, he watched a small party of fallow-deer for some time, as they fed on the hill-side with five of the white cattle; and the keeper, Michie, assured him that both red- and fallow-deer live in perfect harmony with them, and, if in any way alarmed or disturbed, generally seek safety in their company. The editor of the *Zoologist* adds that in Mr. Assheton Smith's park at Vaynol, near Bangor, where he has just spent some weeks, white cattle and red- and fallow-deer roam together, and no such hostility as that above referred to has ever been noticed.

THE collections of the Australian Museum, Sydney, are being steadily increased. In the report of the trustees for 1889, just received, it is stated that the principal purchases during the year were a collection of shells comprising some 15,000 species, and a collection of minerals, including specimens of gold from various parts of the world other than Australia. Several collecting expeditions were sent out with satisfactory results. The principal of these were:—(1) To Mount Kosciusko (Mr. R. Helms, collector), where an extensive collection of insects and other specimens from high altitudes, including many not previously represented in the Museum, was obtained. (2) To the Bellenden-Ker Ranges, north-eastern Queensland (Messrs. E. J. Cairn and R. Grant, collectors). This expedition obtained many rare mammals and birds of interest, including the remarkable tree kangaroo (*Dendrolagus lumholtzi*), and a new species of Petaurista, as well as a recently described new bower bird. (3) To Mount Sassafras, Shoalhaven District (Mr. R. Etheridge, palæontologist, and Mr. J. A. Thorpe, taxidermist, acting as collectors). This journey was undertaken with the view of obtaining some aboriginal remains, said to be concealed in a rocky recess at Mount Sassafras. The expedition was successful in obtaining the remains sought for, and in other ways. (4) To Blackhead, Illawarra District (Mr. A. J. North acting as collector). This was a short trip, to obtain certain fossils which were required to fill gaps in the collections. Abridgments of the reports of these various expeditions will be found in the first number of "The Records of the Australian Museum."

AT the request of Prof. Baird, Mr. William Palmer accompanied the United States Fish Commission schooner *Grampus* on her summer cruise in 1887 for the purpose of observing and collecting the fish-eating birds, together with their eggs and young. Mr. Palmer contributes to the Proceedings of the United States National Museum (vol. xiii., pp. 249–265) a record of his observations, and this has now been printed separately. He treats each species briefly. As all on board were interested in the matter, and frequently called his attention to birds seen by them, he believes his list contains all the species that came within a reasonable distance of the vessel. It might naturally be supposed that on a cruise of this character sea-birds would be found to be generally numerous, but such was not the case. With few exceptions, and these mainly on breeding islands, birds were very scarce, most of the many species having completed their migrations, and being in the far north or inland. As to the relative abundance of the species, Mr. Palmer places the most prominent in the following order: puffins, shearwaters, black hagdons, murres, and gannets. Good skins were made of the greater number of the species, and in many cases, also, eggs, embryos, and young in various degrees of plumage, were obtained. The localities visited were as follows: the Magdalen Islands and Bird Rocks, in the Gulf of St. Lawrence; St. John's; Funk Island; Seldom Come By; Cape Freels Penguin Islands; Toulinguet and Canada Bay, in Newfoundland; Black Bay and Mingan Islands; Southern Labrador, and Percé, Canada. The time covered was from July 8 to August 31.

MR. J. M. COODE records, in the new number of the Journal of the Bombay Natural History Society, the following instance of an exceptional method of hunting which the panther is occasionally forced to adopt. Mr. Coode was lately asked by the Patel of a village in the Amraoti district to accompany him one evening to a forest nursery of young bamboo shoots, to assist in killing a large boar which nightly visited the place and did immense damage. They waited for some time, when, just as is was getting dark, they heard the short guttural sound of a panther and heavy footfall of some running animal. The noises came nearer and nearer, until a nilghai and a panther could be distinctly seen against the sky-line, the former being chased by the latter. The nilghai kept moaning, and was evidently in an abject state of fear. The two ran round in a circle of about 160 yards diameter, within 30 yards of where the observers were standing, and passed them twice, both animals making their respective noises. They then disappeared, but Mr. Coode has reason to believe the nilghai got away.

THE following are the principal contents of the Journal of the Bombay Natural History Society (No. 3, vol. v.):—On new and little-known butterflies from the Indian region, with descriptions of three new genera of Hesperidæ, by Lionel de Nicéville (with plates); Bombay grasses (Part 2), by Dr. J. C. Lisboa; on new and little-known Hymenoptera from India, Burma, and Ceylon, by Major C. T. Bingham, Forest Departments, Burma (with plates); mules, by J. H. Steel; notes on the larvæ and pupæ of some of the butterflies of the Bombay Presidency, by J. Davidson and E. H. Aitken (with plates); the butterflies of the Central Provinces (Part 3), by J. A. Betham; notes on the economic botany of the Cucurbitaceæ of Western India, by Dr. W. Dymock; list of Chin-Lushai butterflies, by Lionel de Nicéville.

MESSRS. R. FRIEDLÄNDER AND SON, Berlin, have just issued a catalogue of books relating to Invertebrata. It includes a very large number of important works on the special branch of zoology to which it relates.

IN our fifth note, on November 27, p. 87, *for* Friana *read* Triana.

AN important paper is contributed by MM. Barbier and Roux to the current number of the *Bulletin de la Société Chimique*, in which are described the final results of an elaborate experimental investigation concerning the relations between the optical dispersive power of the alcohols, ethers, and fatty acids, and their molecular weight and constitution. The relations brought to light, as might perhaps have been expected, are of the most regularly systematic character, and capable of expression in a few simple generalizations. The experimental portion of the work consisted in determinations of the refractive indices of the liquid in question at known temperatures, and for two widely separated lines of the spectrum of wave-lengths λ_a and λ_b. A measure of the dispersive power is then afforded by the amount of the difference between the values of the two indices thus obtained. It has also been shown that if the well-known expression of Cauchy, $n = A + \frac{B}{\lambda^2} + \ldots$, for the refractive index n be adopted, and for all practical purposes the expression appears to be sufficiently approximate, the constant B is a true measure of the dispersion. This value B is termed by MM. Barbier and Roux the dispersive power. In order, however, to eliminate differences due to the unavoidable differences of temperature at which the various determinations are made, the conventional expression $\frac{B}{d}$, where d represents the density of the liquid at the temperature of observation, is employed in the comparisons, and is called the specific dispersive power. The value of B is readily calculated from the two determinations of refractive index by means of the formula—

$$B = \frac{n_a - n_b}{\frac{1}{\lambda_a^2} - \frac{1}{\lambda_b^2}}$$

The general conclusion arrived at from the experiments upon the alcohols is that "the dispersive powers are continuous functions of the molecular weight, and they increase with increasing molecular weight in the fatty series, and decrease with ascending molecular weight in the aromatic series." Similarly as the result of the investigation of the ethers, it was found that "the value of the dispersive power augments with the molecular condensation." It was further remarked that "the values of the dispersive powers of isomeric ethers are practically identical." In illustration of this latter point, which appears to show that the dispersion practically depends alone upon the molecular weight of the substance, it may be noted that ordinary ether, ethyl oxide, and the isomeric mixed ether, methyl propyl oxide, both possess the same dispersive power, as do also propyl ether, ethyl isobutyl ether, and methyl isoamyl ether. It was also curiously observed that in the mixed ethers of the series $\left.\begin{matrix}(C_nH_{2n-1})\\(C_nH_{2}+1)\end{matrix}\right\rangle O$, in which the unsaturated allyl radicals occur, the specific dispersive power is approximately the same for all the members of the series, while for the mixed ethers of the series $\left.\begin{matrix}(C_nH_{2n-7})\\(C_nH_{2n+1})\end{matrix}\right\rangle O$, in which the still further unsaturated aromatic radicles are introduced, the value actually diminishes as the molecular weight increases. The very important conclusion was also arrived at that the specific molecular dispersive power $\frac{B}{d}M$, where M represents molecular weight, of a compound is equal to the algebraic sum of the specific molecular dispersive powers of its constituents. Precisely analogous results were obtained from the experiments upon the liquid fatty acids, confirming the main generalization that dispersion is a true function of the molecular weight.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus* ♂) from North Africa, presented by Madame Ruoy; a White-fronted Capuchin (*Cebus albifrons* ♂) from South America, presented by Mrs. Akers-Douglas; a Pinche Monkey (*Midis œdipus* ♀) from New Granada, presented by Mr. J. Barry O'Callighan; a Himalayan Bear (*Ursus tibetanus* ♀) from Beloochistan, presented by Mr. B. T. Ffinch, C.M.Z.S.; a Common Raccoon (*Procyon lotor*) from North America, presented by Mr. C. E. Brewerton; a Greater White-crested Cockatoo (*Cacatua cristata*) from Moluccas, presented by Mr. C. J. Cassirer; a Blue and Yellow Macaw (*Ara ararauna*) from Brazil, presented by Mr. A. Cohen; a Pennant's Parrakeet (*Platycercus pennanti*) from Australia, presented by Mrs. Moon; a Water Rail (*Rallus aquaticus*), British, presented by Mr. T. E. Gunn; two Alligators (*Alligator mississippiensis*) from Florida, presented by Mr. Henry Birkbeck; two —— Snakes (*Pituophis melanoleucus*) from New Jersey, U.S.A., presented by Mr. Morton Middleton; two Snow Buntings (*Plectophanes nivalis*), European, purchased; a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE PHOTOGRAPHY OF SOLAR PROMINENCES.—Mr. G. E. Hale, of Kenwood Physical Observatory, Chicago, describes in *Astronomische Nachrichten*, No. 3006, the results of some attempts made last winter to photograph solar prominences. One of the methods employed is to alter the rate of the driving clock of the equatorial, so that a prominence may move slowly across the slit of a spectroscope adjusted radially on the sun's image. A prominence line, say C, is brought into the centre of the field of the observing spectroscope, and at the same time falls upon a photographic plate having a motion such that the radius of curvature of the sun's limb upon it is the same as that of the focus of the equatorial.

A second method proposed is to use a stationary solar image and photographic plate, with two slits in uniform motion—one the radial slit of a spectroscope, the other a slit moving directly in front of the plate.

The plates have been stained with cyanin, alizarin, and erythrosin for the photography of the prominence lines C and D_3, utilized in the experiments. The work is to be resumed shortly with a rotating cylinder, having upon its circumference a strip of dyed celluloid film moving across the focus of the observing telescope, instead of the plates previously used. If this be done, and a uniform motion given by a good clock or clepsydra, some definite results may be expected.

THE FREQUENCY OF METEORS.—MM. Terby and Van Lint made some observations of the relative frequency of meteors on August 9 and 10, 1890 (*Bulletin de l'Académie Royal des Sciences, Brussels*, No. 9, 1890). An inspection of the observations tabulated shows that before midnight an observer whose field of view embraced one fifth of the horizon, saw from three to five meteors in fifteen minutes. This number was increased after midnight, however, so that an observer, viewing one-sixth of the sky, saw from five to six meteors in the same interval. On August 10 a maximum appeared to be reached between 12h. 30m. and 13h. 11m., the average in that interval being one in two minutes. Only two meteors were observed whose briliancy was comparable with that of Jupiter. The trains were few, and of short duration.

THE ANNIVERSARY OF THE ROYAL SOCIETY. [1]

THE proceedings of every anniversary meeting remind us of the losses which the Society has sustained during the preceding year by the deaths of several of its Fellows. Of

[1] Presidential address delivered by Sir George Stokes at the anniversary meeting, December 1.

those whom we have lost during the past year, some were distinguished for their scientific labours, some were well known in the world at large. Of several, full obituary notices have appeared or will appear in the Proceedings, but it will, I think, be in accordance with the wishes of the Fellows that I should say a few words on the present occasion about some of those whom we have lost.

The Rev. Stephen J. Perry, S. J., whose name is well-known in connexion with his accurate magnetic observations, and his labours in the domain of solar physics, was last year elected a member of the Council. It was known that he could not attend the first meeting, for he would be on his way to the West Indies to observe the total solar eclipse of the 22nd of December, but we looked forward to having him at the meetings of our Council after that was over. In this we were doomed to disappointment, for a telegram which arrived shortly after the day of the eclipse brought the sad intelligence of his death. His illness began shortly before the day of the eclipse, but he did not suffer it to interrupt his preparations, but worked on to the end as far as his failing strength would allow. The observation of total solar eclipses was a branch of solar physics to which he had paid special attention, and, considering the circumstances of his death, we may regard him as a martyr to science, while at the same time his kindly disposition ensured attachment from all who knew him.

William Lewis Ferdinand Fischer, who was a friend of mine for more than forty years, was a German by birth, and was educated in that country. He came to Cambridge later in life than most men commence residence, entering at my own college, Pembroke. At the time when he entered he was only imperfectly acquainted with the English language. He took his degree in due course, having come out fourth wrangler. He obtained a fellowship at Clare College, and, after some time, was elected Professor of Natural Philosophy in the University of St. Andrews, at which town he continued to reside till his death, and his widow still resides. He was remarkably well acquainted with what had been done in physical science.

In the middle of January we lost, in Lord Napier of Magdala, a man of world-wide reputation, who had been a Fellow of the Society for more than twenty three years. A sketch of his life has already appeared in the Proceedings.

The eminent physician Sir William Gull, who for some considerable time had been in failing health, was taken from us at the beginning of this year. The Fellows have already in their hands a sketch of his life.

In February there died, at an advanced age, our Fellow Sir Robert Kane, who was eminent among what we may regard as the last generation of chemists. A biographical notice of him is already in the hands of the Fellows.

Robert William Mylne, who died in July, was twelfth in direct descent of a family of architects and engineers, his direct ancestor having had the erection of new buildings for Holyrood Palace in the reign of Charles the Second. He had still in his possession the correspondence relating to that work. His own work lay chiefly in hydraulic engineering and the geology of the south-east of England, especially the London area, and in advising respecting the construction of new buildings in the City.

General Sir John Henry Lefroy, who died last April, combined the duties of his profession and of his responsible offices as Governor of Bermuda, and, for a time, of Tasmania, with active scientific work in relation especially to terrestrial magnetism, with which he was connected by his post as director of magnetic observations at St. Helena and at Toronto. He is the author of a treatise on the subject, and has entered into some investigations bearing on a possible cause of local magnetic irregularities, which seem well deserving of consideration.

Sir Warington Wilkinson Smyth, who was so high an authority on all that relates to mining, and geology as bearing upon it, was one of our Fellows who repeatedly served on our Council and on various committees, and by his sound judgment aided us in our deliberations. Though his health had been failing for some time, his end came upon us with startling suddenness. It will be remembered by many of the Fellows that he was present at our *conversazione* on 18 June, and next morning he breathed his last. He was widely known as a man of science, and was honorary Fellow of various societies on the Continent. In him I have lost one who was formerly a colleague of my own as lecturer in the School of Mines.

William Kitchen Parker held a very high place among biologists in relation especially to the homologies of the vertebrate skeleton. Notwithstanding the laborious nature of his profession, he managed to find time for his scientific pursuits, and our Transactions contain a large number of papers which came from his pen, and are illustrated by elaborate drawings. So highly were his biological researches thought of, that for several years means were found, through an application of a portion of the Government Grant, for enabling him to dispense with the laborious work of his profession, and devote himself to science. His genial disposition and vivacity of manner, and, curiously enough, his personal appearance, reminded one of Faraday.

Dr. James Matthews Duncan, who died suddenly from heart disease, was eminent as an obstetric physician, and was a man of singular straightforwardness of character.

Our Fellow Charles Handfield Jones died on September 30. His chief scientific labours lay in the domain of pathological anatomy.

Alexander John Ellis, who died on October 28, devoted great attention to philology and to the theory of the perfection of musical sounds, and translated v. Helmholtz's work, "Tonempfindungen." He had, shortly before his death, received an honorary doctor's degree from the University of Cambridge.

During the last year we have lost two out of our three senior Fellows, Christopher Rice Mansel Talbot, a Fellow also of the Linnæan Society, who was elected our Fellow in 1831, and, still more recently, in fact only a few days ago, Sir John Francis Davis, who was elected as long ago as 1822, and died at the very advanced age of ninety-six.

The number of Fellows elected before 1847 is now reduced to eighteen, so that in any statistical calculations of the effect of the statutes of 1847 on the number of Fellows, the present condition of the Society may be taken as practically normal.

The Committee appointed in 1888 to consider the best mode of administrating the fund, which was inaugurated in 1882, for founding a memorial to our late eminent Fellow, Charles Darwin, have now presented their report, which has been adopted by the Council. It has been decided that the proceeds of the Darwin Fund be for the present applied biennially in reward of work of acknowledged distinction (especially in biology) in the field in which Mr. Darwin himself laboured; that the award consist of a medal in silver or bronze, accompanied by a grant of £100; that it be made either to a British subject or to a foreigner, and without distinction of sex; and that the award should be conferred at the same time as other medals at the anniversary.

It was further intended, in accordance with Mr. Darwin's known views, that, as a rule, the award should be made rather for the work of younger men in the early part of their career than as a reward to men whose scientific career is nearly finished.

The Committee appointed at a meeting of the Council held immediately before the last anniversary meeting of the Society, to set on foot a memorial of our late Fellow James Prescott Joule, have naturally not got quite so far in their work. They decided that the memorial should take an international character, and should have for its object the encouragement of research in physical science, and should also have in view the erection of some personal memorial in London. The subject was accordingly brought to the notice of a number of scientific men abroad, from many of whom favourable replies have been received. The Joule Committee have resolved, "That the balance of the fund, after providing a suitable personal memorial, be transferred to the President, Council, and Fellows of the Royal Society, and that the President and Council be requested to undertake the administration of the proceeds in such manner as may appear to them most suitable for the encouragement of research, both in England and abroad, especially among younger men, in those branches of physical science more immediately connected with Joule's work;" and, also, "That the treasurer be instructed to retain for the present a sum not exceeding £300 for the expenses of the medallion, and hand over the balance to the President, Council, and Fellows of the Royal Society."

This offer of the Joule Committee was accepted with thanks by the Council, but the further consideration of the steps to be taken has not yet been entered on. Meanwhile the treasurer of the fund has handed over to the treasurer of the Royal Society a sum of about £1,400.

In 1663, when the second charter was granted to the Society, a body of statutes was drawn up for regulating various matters not fixed by charter. Alterations have since been made from time to time, as provided for in the statutes themselves. The last considerable alteration was made in 1847, when the present system was introduced, according to which the Council select from the candidates, other than those who have a special privilege as to coming on for ballot, a definite number whom they recommend to the Society for election, and the election takes place on one definite day in the year. A few changes, of less importance, have been made since that time, and experience has pointed out the desirability of some changes of detail, chiefly as regards the mode of dealing with papers. A committee was appointed last session, and continued at the commencement of the present, to revise the whole body of statutes, with a view to bring them into stricter conformity with existing practice, and at the same time to propose further changes, should any such appear desirable. The Committee have now reported ; but as the session was near its end, and the subject was one requiring full consideration by the Council, the report has been merely received and entered on the minutes, and it has been left to the Council that is to be elected to-day to take such further steps as may appear to them desirable.

Some of the proposed alterations relate to the mode of dealing with papers which are communicated to the Society, which is a matter of practical business that may well be left to the judgment and experience of the executive body. But some points have been raised which it seems desirable to bring to the notice of the Fellows at large, in order that they may have an opportunity of considering them before a final decision is come to by the new Council.

The question has more than once been raised whether, considering the increase of population and the more general diffusion of scientific knowledge which has taken place within the last forty years, the number of candidates to be selected by the Council for recommendation to the Fellows for election might not now, with advantage, be made a little larger than fifteen, the number at which it was fixed in 1847. On this question there was considerable difference of opinion in the Committee, but the majority were in favour of keeping the number as it is at present.

Connected, to a slight extent, with this question is another, whether the Council should not have the power of recommending to the Fellows for election, in addition to the fifteen selected from among the candidates on the ground of scientific merit, a strictly limited number of men of very high eminence in other ways. The Committee recommend that such a power be entrusted to the Council, the number of Fellows who have been thus elected, existing at any time, being limited to a maximum of twenty-five, and the number elected in any year to a maximum of two.

The question was also discussed whether the maximum number of foreign members, which at present stands at fifty, should be increased, and was decided in the negative.

Another recommendation of the Committee which perhaps it may be as well to mention, is one enabling the Council, in any year, to regulate for the ensuing year the length of the Christmas and Easter holidays. At present the weekly meetings are resumed in the second week after Christmas week, and there is then no intermission till Passion week, though the earlier portion at least of this interval is a time during which papers intended for reading do not usually come in so frequently as towards the end of the session. According to the statute in force till 1888, three of the ordinary weekly meetings between Whit-Sunday and the last meeting in June, were cut out by the Whitsun holiday, Ascension Day, and the annual election of Fellows ; and as at that time of year papers commonly come in pretty frequently, there was a considerable congestion of papers towards the close of the session. This congestion was partially relieved by an alteration of the statutes, which came into force in 1888, enacting that an ordinary meeting should be held at the conclusion of the Annual Meeting for the election of Fellows ; but the fact that the proportion between the number of meetings held and the number of papers that come in varies a good deal with the season, seems to render it desirable that the regulation of the number of meetings should be rather more elastic, and should to some extent be left in the hands of the Council.

Since the last anniversary twenty-five memoirs have been published in the Philosophical Transactions, containing a total of 1068 pages and 72 plates. Of the Proceedings, eleven numbers have been issued, containing 1165 pages.

In the library, the work of making room for growing series, and of obtaining volumes or parts to complete series that were imperfect, has been continued. In the course of this work the Council have, upon the recommendation of the Library Committee, distributed some 1500 volumes, consisting partly of duplicates and partly of works of small scientific value, among various public institutions. The catalogue of the manuscripts, which I mentioned in my last year's address, as about to be commenced, has been completed during the past session. The maps and charts, the pictures and busts, have also been catalogued, and the collection of the manuscripts of memoirs in the Philosophical Transactions, the Proceedings, and the Archives, having been completed, the binding of them is now going forward.

With a view to increasing the circulation of the Society's publications on the Continent of Europe, Messrs. Friedländer and Son, of Berlin, have lately been appointed additional agents for their sale.

The Royal Society has always been ready to assist the Government of the day when requested so to do, by expressing its opinions or offering its advice on questions involving special scientific knowledge. Last year I received, as your President, a request from the President of the Board of Trade that I should, in conjunction with two Fellows of the Royal Society nominated by me in consultation with the Council, examine a report in two parts presented by the Corporation of the Trinity House to the Board of Trade, relative to lighthouse illuminants, and express our opinion whether the conclusions of the Trinity House, as set forth in their Reports, are justified by the records of the experiments contained therein. Lord Rayleigh and Sir William Thomson were asked, and consented to join me as referees, and our Report was some time ago sent in to the Board of Trade.

Another subject in which scientific principles are blended with practical application, is that of colour blindness in its relation to the correct perception of coloured signals used at sea and in the railway service. It is easy to understand what serious accidents might be occasioned, for instance, by confusing red with green ; and so well is the liability to such confusion, arising from a not very rare abnormal condition of colour perception, understood at the present day, that persons who propose to engage in service at sea or on the railways are now, as a matter of course, examined as to their perception of colour. But, glaring as the difference between red and green appears to persons whose vision is normal, the detection of those who are liable to confound them, and who, for the most part, are quite unconscious that they see colours differently from people in general, is by no means so easy as it might appear at first sight ; and there appeared reason to think that sometimes the tests applied are defective, and let pass persons who are afflicted with this peculiarity of vision, while, on the other hand, they may lead to rejection of persons whose vision is normal, perhaps, after they have engaged in their course for life in an employment for which normal vision is demanded. Mr. R. Brudenell Carter wrote a letter to us suggesting that we should appoint a committee to investigate the subject of colour blindness, and after discussion of this proposal I was requested to write a letter to the President of the Board of Trade informing him that, should the Government desire it, the Council will be prepared to appoint a committee to consider the whole question of colour blindness. A reply was received from the Board thanking us for the communication, and saying that they regarded with satisfaction the proposal of the Council to appoint such a committee. A committee has accordingly been appointed, and has held several meetings, and examined several witnesses ; but the subject is a wide one, and the committee have not yet brought their labours to a close.

The proceedings of to-day bring to an end my long tenure of office in the Royal Society, which has extended now over thirty-six years, during the last five of which I have held the honourable office of your President. I am deeply sensible of the kindness which I have always experienced from the Fellows, and of the indulgence with which they have overlooked my deficiencies, due, in part, to the pressure of other work. It cannot be without a strong feeling of regret that I come to the close of an official connection with the Society that has now extended over full half my life. But I feel that it is time that I should make way for others, and that I should not wait for those infirmities which advancing years so often bring in their train ; besides which, there are personal reasons which led me to request the members of the Council not to vote for my nomination for re-election as your President.

And now it only remains to me, as virtually my last official act as your President, to perform the pleasing duty of delivering the medals which the Society has to award to the respective recipients of those honours.

The Copley Medal has been awarded to our Foreign Member, Prof. Simon Newcomb, who has been engaged during the last thirty years in a series of important researches, which have contributed greatly to the progress of gravitational astronomy. Among his labours in this field may be mentioned his able discussion of the mutual relations of the orbits of the asteroids, with reference to Olbers' hypothesis, that they were formed by the breaking up of a ring of nebulous matter, his discussion of the orbits of Uranus and Neptune, and of the orbit of the moon. Recently he has turned his attention to Saturn's satellites, and has investigated the remarkable action of Titan on Hyperion. For many years back he has chiefly been engaged in perfecting the tables of the moon; and in his important work, "Researches on the Motion of the Moon," he has discussed observations of eclipses and occultations previous to 1750, with the important practical result that, by the removal of an empirical term of long period from Hansen's lunar tables, and by an empirical alteration of another term of long period, he is enabled to represent satisfactorily the observations of the moon from 1625 to the present time; and by thus indicating empirically the long period inequality required to represent the moon's motion, he has prepared the way for its theoretical investigation.

The Rumford Medal has been awarded to Prof. H. Hertz for his work on electro-magnetic radiation.

One of the most remarkable achievements of the late Prof. Clerk Maxwell was his electro-magnetic theory of light, in which it was shown that a certain velocity, determinable numerically by purely electrical experiments, and expressing theoretically the velocity of propagation of an electro-magnetic disturbance, agreed within the limits of error of experiment with the known velocity of propagation of light; and accordingly that we have strong reason for believing that light is an electro-magnetic phenomenon, whatever the appropriate physical idea may hereafter prove to be which we ought to attach to the propagation of an electro-magnetic disturbance. But as yet no means existed by which phenomena, such as those of interference, which are bound up with the propagation of undulations, could be exhibited by purely electrical means. Prof. Hertz was the first to detect electro-magnetic waves in free space by his invention of a suitable receiver, consisting of a resonating circuit, which gives visible sparks when immersed in a region of sufficiently intense electric radiation.

By reflection, refraction, and interference experiments, he has further verified the undulatory nature of the disturbance near a quick electric oscillator, such as had been suggested by Prof. Fitzgerald, on the basis of Clerk Maxwell's electro-magnetic theory of light, and Sir W. Thomson's theory of the oscillatory character of a Leyden jar discharge.

These important researches contribute powerfully to the inducements we have to refer the phenomena of light and electricity to a common cause, different as hitherto their manifestations have been; and by this means the theory of each may be advanced through what we know of the other.

One of the Royal medals has been awarded to our Fellow, Dr. David Ferrier, for his researches on the localization of cerebral functions.

We owe to his experiments, and the method of experimenting upon monkeys which he introduced, almost the whole of our knowledge of cerebral localization in man. From pathological observations, Broca located the centre for speech in the third left frontal convolution, but with this exception nothing was known of cerebral localization in man until Dr. Ferrier commenced his experiments in 1873.

Fritsch and Hitzig, in 1870, had observed that definite movements could be obtained by electrical irritation of the cerebral cortex in the dog, and this indicated the existence of localized motor areas in the brain. They did nothing, however, towards localizing sensory centres, and even in regard to the motor centres their observations were very limited. Their observations attracted hardly any attention; they had neither followed them up themselves, nor had any one else taken them up; and when Dr. Ferrier began his experiments he was ignorant of their observations, and discovered the method independently. By the happy device of experimenting upon monkeys, whose brains present a great similarity in the arrangement of the convolutions to those of man, he was able to map out the most important *motor* areas with great precision; but not content with the investigation of motor centres, he experimented on the localization of *sensory* centres in the brain, and not only showed conclusively the existence of such centres, but determined their position. In addition to his work on cerebral localization he has shown, in conjunction with Dr. Yeo, that the complex, and at first sight seemingly purposeless connections of nerve fibres in certain plexuses is really connected with the co-ordination of various muscles for definite purposive movements. As so often happens, these researches, purely scientific in the first instance, have been turned to practical account. Dr. Ferrier himself predicted the application of cerebral localization to cerebral surgery. This application he and others have already made, and his prediction is now being fulfilled with brilliant results.

The other Royal Medal has been awarded to our Fellow, Dr. John Hopkinson, for his researches in magnetism and electricity.

Dr. Hopkinson's researches in magnetism comprise investigations of the effect of temperature upon the magnetic properties of iron, nickel, and various alloys of these metals (Phil. Trans., 1889, A, p. 443). Before these investigations were published it was thought that increased temperature tended to diminish the magnetic susceptibility of iron. Dr. Hopkinson's experiments show, however, that, on the contrary, the magnetic susceptibility increases enormously as the temperature increases, until the temperature reaches about 660° C.; beyond this temperature iron entirely ceases to be magnetic.

Dr. Hopkinson's contributions to the theory of dynamo-electric machinery are most important. The method, now so extensively used, of solving problems relating to dynamos by the use of what M. Deprez has called the "characteristic curve," is due to him.

He has also made a series of determinations of the specific inductive capacities and refractive indices of a large number of transparent dielectrics, the results of which are of great importance in the theories of electricity and light.

The Davy Medal has been awarded to Prof. Emil Fischer for his discoveries in organic chemistry, and especially for his researches on the carbo-hydrates.

To him, in conjunction with Otto Fischer, we owe the determination of the constitution of rosaniline, a most valuable dye-stuff, and the typical member of a very large group of important dyes.

He is the discoverer of phenylhydrazine, one of the most important of the reagents placed at chemists' disposal within recent years, and he has most exhaustively studied the behaviour of this substance and its congeners. The hydrazines have also been employed by Fischer in preparing indole derivatives, among others, skatole, and the study of a class of substances of considerable physiological importance has thereby been rendered possible.

During the past seven years Fischer has devoted his attention to the study of the sugars, and has obtained most marvellous results, having succeeded in preparing, by purely artificial methods, the known sugars dextrose and levulose, as well as other isomeric sugars, and having established the relationship of the various members of the glucose group. He has, in addition, determined the constitution of milk-sugar and of starch-sugar—the isomer of cane-sugar formed on hydrolysing starch. He has also prepared "glucoses" containing seven, eight, and nine atoms of carbon, and has established the remarkable fact that only those which contain three, six, or nine atoms of carbon are fermentable by yeast. His researches are not only of the highest value to chemists, but also of extreme importance to physiologists, on account of the insight which they afford of the processes concerned in the natural formation of sugars.

The Darwin Medal has been awarded to Mr. Alfred Russel Wallace for his independent origination of the theory of the origin of species by natural selection.

It was natural that this, the first award of the Darwin Medal, should have been made to one who independently originated the theory, since named that of natural selection, which, in conjunction with his other numerous and important contributions in the domain of natural history, have made the name of Darwin so famous, and who made known a large series of important and novel observations in support of that theory, the result of many years work in the Malay Archipelago. These views Mr. Wallace has subsequently most ably advocated in various published works, among others his laborious volumes on the "Geographical Distribution of Animals," his brilliant "Island Life," and more recently his "Darwinism," which was published only last year.

WHO ARE THE AMERICAN INDIANS?

ATTENTION has once more been attracted to the American aborigines by the troubles of the United States Government with some of the Indians of Dakota and various neighbouring districts. Special interest therefore attaches to a lecture on the question "Who are the American Indians?" recently delivered by Mr. H. W. Henshaw, in the National Museum, Washington, in the "Saturday Course," under the auspices of the Anthropological, Biological, Chemical, National, Geographic, and Philosophical Societies. The following is the more important part of the lecture:—

When Columbus discovered America he discovered not only a new continent but a new people—the American Indians. From one end to the other of its broad expanse the continent was occupied by Indian tribes that had held the land from time immemorial—so far at least as their own traditions aver—knowing nothing of any country but their own. The commonly presented picture of the Indians as they appeared at the time of the discovery is that of a horde of wandering savages, half or wholly naked, living on roots and herbs, or existing by the capture of wild animals scarcely more savage than themselves, and the chief objects of whose existence was to enslave, to torture, and to kill each other. Those who hold such opinions have ever taken a hopeless view of the Indian's present and a still more hopeless view of his future. Such a picture conveys a totally false impression of the Indian and of the state of culture to which he had attained at the era of the discovery. Though still living in savagery, he was in the upper confines of that estate, and was fast pressing upon the second stage of progress, that of barbarism—that is to say, he had progressed far beyond and above the lowest states in which man is known to live, to say nothing of the still lower conditions from which he must have emerged, and had travelled many steps along the long and difficult road to civilization.

Already he had become skilful in the practice of many arts. Though the skins of beasts furnished a large part of his clothing, he had possessed himself of the weaver's art, and from the hair of many animals, from the down of birds, and from the fibres of many plants he knew how to spin, to weave, and to dye fabrics.

Basket-making he had carried to so high a degree of perfection that little further improvement was possible.

The potter's art also was his, and though his methods were crude and laborious, the results achieved, both as regards grace of form and ornamentation, may well excite admiration at the present day.

Copper had been discovered and was mined and roughly beaten into shape to serve for ornament and, to some slight extent, for mechanical use. In Mexico and Peru, gold, silver, and copper were worked, and many authors contend that the method of making bronze, an invention fraught with tremendous possibilities, had there been discovered.

In much of South and Central America, Mexico, and the eastern parts of the United States, so important an advance had been made in agriculture that it furnished a very large part of the food supply, and it should not be forgotten that the chief product of the Indian's tillage, maize or Indian corn, which to-day furnishes a large part of the world's food, was the gift of the Indian to civilization. A scarcely less important contribution to mankind is the potato, the cultivation of which also originated with the Indians. A third important agricultural product, though less beneficial, is tobacco, the use and cultivation of which had been discovered centuries before the advent of the European.

Architecture may seem like a large word to apply to the dwellings of the Indians. Nevertheless many of their houses were more substantial and comfortable than is generally supposed, while in the North-West many tribes reared dwellings of hewn planks, sometimes as large as 210 feet long by 30 feet wide, which were capable of accommodating several hundred individuals. More pretentious and durable were the communal houses of mud and stone reared by the Pueblo people of Arizona, New Mexico, and Mexico, while further south, in Central and South America, were edifices of hewn stone, which from their dimensions, the size of some of the blocks contained in them, and the extent and ornate character of the ornamentation, justly excite the wonder and admiration of the traveller and archæologist.

The advantages of a beast of burden had been perceived, and though the human back furnished by far the greater part of the transportation, yet in North America the dog had been trained into an effective ally, and in the Andes the llama performed a similar office. Insignificant as was the use of the dog as a carrier, its employment cannot well be over-estimated as a step in progress when it is remembered that the plain's tribes that most employed it lived in the midst of the buffalo, an animal which must have become of prime domestic importance in the never-to be-enacted future of the Indian.

The need of some method of recording events and communicating ideas had been felt, and had given rise, even among the ruder tribes, to picture-writing, which in Mexico and Central America had been so far developed into ideographs, popularly called hieroglyphics, as to hint strongly at the next stage, the invention of a true phonetic alphabet; nay more, the Mexicans and Mayas are believed to have reached a stage of true phonetic writing, where characters were made to represent not things, as true ideographic writing, but the names of things and even of abstract ideas; and this is a stage which may be said to be on the very threshold of one of the proudest achievements of civilization, that of a phonetic alphabet.

Instead of living in an unorganized state, where each man was a law unto himself in all things, the Indians lived under organized forms of government, rude enough indeed when compared with the highly organized system of civilized nations, but marking an essential advance on the conditions attained by savage peoples in other parts of the world. The chieftaincy was transmitted by well understood laws, or, as in some tribes, was more purely elective. Their social system was very ingenious and complex, and, being based largely upon kinship ties, was singularly well fitted for the state to which they had attained, of which indeed it was simply an expression and outgrowth. In many sections a considerable advance had been made in political confederation, and neighbouring tribes combined for defence and to wage war against a common enemy. They had invented many and singularly efficient laws to repress and punish lawlessness against the individual and the social body, and as a consequence they enjoyed almost entire immunity from theft and many other crimes.

The development of religious ideas among our Indians is a curious and instructive study. Though the Great Spirit and the Happy Hunting Ground which missionaries and theologians thought they had discovered among them are now known to have had no existence, the Indians had by no means reached the state of culture in which they were found without developing religions. Their gods or fetishes were innumerable, their priests endowed with immense influence, and their ceremonies of devotion and propitiation were as devout as they were elaborate. The precision of the beliefs of many tribes and the elaborateness of their rituals are simply astonishing. Thus their advance in the domain of religious thought equalled, if it did not surpass, their progress in some other directions.

If by medicine we mean the rational treatment of disease, the Indian can be said to have learned only the rudiments of the healing art. Medicine, in so far as it was a distinct profession, was almost wholly in the hands of the Medicine Man or Shaman, who filled the twofold office of priest and doctor. Neither the theory nor the practice of the Shaman had in it anything that was rational and very little that was efficacious, except through the influence exercised over the mind of the patient—in other words, except so far as the Shaman was a faith-curer. Whatever that is marvellous in the modern cases of faith-cure can be more than matched out of the practice and experience of the Shaman, who learned his trade long before the European came to these shores. He who would see the Indian Shaman need not seek the wilds of the Far West. He may find his counterpart on Pennsylvania Avenue. The whole medical practice of the Indian Shaman was based upon the idea that all disease was the effect of evil disease spirits that had obtained lodgment in the body, or that it was caused by witchcraft, and so long as practice was directed to the dislodgment of these spirits no rational treatment was possible. I am aware that the above idea of Indian medicine is contrary to popular belief, which to some extent at least is in harmony with the claims of alleged Indian doctors of white extraction who claim to have derived their skill and their herbs directly from the hands of Indian experts. Recent and carefully conducted investigations on this subject, however, fully substantiate the above statements. Though roots and herbs were employed in the treatment of nearly all diseases, they were chiefly used as adjuncts to the harms and sorceries of the medicine man. Often they were not given to the patient at all, but were taken by the medicine man to heighten his power over the disease spirits. Often they were applied by being rubbed on the body of the patient or by being blown in the shape of smoke on the afflicted part.

Among the Indians was found flourishing to a remarkable degree the so-called doctrine of seals or signatures. A few examples of the doctrine derived from the eastern Cheroki by Mr. James Mooney may prove of interest. Doubtless you are all familiar with the cone flower. The Cheroki call it deer eye, and from its fancied resemblance to the strong-sighted eye of the deer and its connection by name, for the Indian believes that there is a potent connection between the name of a thing and the thing itself, it is used as a wash for ailing eyes.

The common purslane (*Portulaca oleracea*) is used as a vermifuge, because the red stalk looks like a worm.

An infusion of the roots of the hoary pea (*Tephrosia virginiana*), called devil's shoe-strings in the South because of their toughness, is used by the Cheroki ball-players as a wash to strengthen their bodies, and by the women as a hair wash to strengthen it and keep it from falling.

Who of you has ever walked in our woods without getting on his clothing the common beggar's lice (*Desmodium*)? How tenaciously they stick you all know; so do the Cheroki, and because the burrs stick fast they use a tea made of them to strengthen the memory. The Cheroki at least can dispense with the services of a Loisette.

You whose ambition it is to be good singers have only to drink a tea of crickets, according to the Cheroki, for does not the cricket possess a fine voice and doth he not sing merrily?

The tendency of the human mind to speculate and to draw inferences—a tendency common alike to the savage and the civilized man—cannot be held in check forever, however strong the bonds; and just as knowledge and science escaped from priestly thrall within the history of civilized times, so a certain small amount of knowledge of the therapeutical use of drugs was gaining ground among the common folk of the Indians. It was fairly to be called old women's practice, as it was largely in their hands. It grew out of observation; infusions of certain herbs produced certain results, acted as emetics or purgatives, and hence these herbs came to be employed with something like an intelligent purpose. Many of the herbs used were absolutely inert; many were harmful, of course, since where there is practically no true diagnosis and no correct knowledge of the effect of drugs there can be no really intelligent selection of remedies; but in the case of certain simple diseases, herbs, the actual cautery, and above all the sweating process, were beginning to be recognized by the common folk as serviceable, and to be employed to some extent without recourse to the Shaman.

As the child must creep ere it can walk, in such theories and treatment, childish though they may seem, may be discerned the beginnings of the noble science of Medicine, which, having largely cast aside the superstitions that hampered her infant steps, now walks erect, and although of late she seems to have revived the beliefs of her childhood, her handmaiden, Science, bids her call the demon disease spirits ignorance and vicious habits, the diseases themselves bacilli or germs. The Indian believes that the white man carried the spirit of small-pox in bottles, and let it loose among them. Modern science actually does bottle the small-pox germs, and germinates them at will. So the Indian theory of disease reappears in a new form.

Such in briefest outline are some of the achievements of the Indian as he was found by civilized man. Whatever value may be placed upon them, whatever rank may be assigned them in the scale of human efforts, they were at least his own, and some of them compare favourably with the record of our Aryan ancestors before they split up into the numerous nations which have done so much to civilize the world. Many, I am aware, hold that the Indian had progressed as far towards civilization as his capacities admitted; others have held, and possibly some now hold, that he was already on the decline; they see in his crude ideas and rude inventions only the degradation of a higher estate; in other words, instead of a savage preparing to enter civilization through the necessary half-way state of barbarism, he is held a half-civilized man lapsing into savagery. Such views, it is needless to say, find no favour in the mind of the evolutionist. To him, the achievements of the Indian are only the milestones which have marked the progress of every civilized nation in its march from what it was to what it is; to him the chief value and significance of his studies of the mental state of the Indian, as expressed in his mythology, his medicine, his social and political organization, or in his more concrete arts, is the fact that in them he reads the records of his own past. If there be any truth whatever in the theory of evolution as applied to human progress, only one inference can be drawn from the history of the Indian race as it appears in historical pages and in the no less eloquent records interpreted by archæologists. This inference is that, starting in its career later than some other races, or being less favoured by circumstances or conditions of environment, or possibly being less endowed, the Indian, despite all, had progressed an immense distance towards civilization; that the race contained all the capabilities for a further advance, and for achieving a civilization of its own, differing, it may be, markedly from our own, as other civilizations differ, but still containing within itself all the essentials of that wonderfully complex thing called civilization. Such at least is the lesson evolution teaches.

Hardly had the new land been discovered when the question arose, Who are the Indians and where did they come from? Naturally enough the Indian had his own answers to these questions. As to who they are all tribes agree. "We are men," said the Illinois to the French; and the name of every tribe in America—the name by which they know themselves—signifies "true men," "men of men," "the only men," as evincing their superiority to all others. As to their origin, their ideas are as confused and perplexing as they are multifarious and conflicting. It may almost be said, as many tribes so many origins. A large number of tribes claim to have originated in the localities where they were first found by Europeans, where they emerged from the ground or came from the recesses of some neighbouring mountain. The Chocta, for instance, claim to have come from an artificial mound in Mississippi. The mound has a depression at its centre which is accounted for by the Creator stamping upon it to close the aperture when he saw that a sufficient number had emerged to form the Chocta tribe. One of the Shawni tribes was created from the ashes of the fire. The Yuchi, of Georgia, claim to be children of the sun, who is their mother, and the earth, their father, an exact reversal of the usual parentage. The Pomo, of California, claim that their ancestors, the Coyote men, were created directly from a knoll of red earth. The Klamath, of Oregon, were made from the service berry. The Yokut, of California, emerged from badger holes, as their name implies. Somewhat more poetical is the idea of the Aht, of Vancouver Island, who allege that animals were first created at Cape Flattery, and from the union of these with a star that fell from the skies resulted the first men, their ancestors.

The above are fair examples of the ideas entertained by the Indians respecting their own origin. Puerile they certainly are, yet who will maintain that they are more so than the theories of origin held by the Greeks and other classical peoples?

Who, then, are the American aborigines? For Columbus and his followers there was but one answer to the question. As he had reached the eastern shores of India the people must be Indians, and his error is perpetuated to-day in the name. Later, when the newly discovered country was found to be not an old but a new continent, the question of the origin and consanguinity of the Indians was renewed. So strongly tinged with religious thought was the philosophy of the day that Biblical sources were naturally first appealed to to solve the knotty problem. As mankind was supposed to have originated in Asia, and as all but the ten lost tribes were accounted for, they were rationally appealed to for the origin of the Indian. Perhaps the best exponent of the belief in the Jewish origin of the Indians was Adair, who published his celebrated essay in 1775. Thoroughly familiar with Indian beliefs and customs, he succeeded in bringing together a mass of evidence, derived from a comparison of religious rites, civil and martial customs, marriages, funeral ceremonies, languages, and traditions, as curious and contradictory as it is inconclusive.

The Jewish origin of the Indians secured a very strong hold on the minds of the writers and thinkers of the eighteenth century, and so firmly did the theory take root that it has never been wholly given up, but is held to-day by a greater or less number as the only rational belief.

Though the favourite, the Jewish hypothesis is by no means the only one. Men of science and laymen count their theories by the score. The Bible and ancient philosophy alike have been appealed to in support of pet hypotheses.

One believes America to have been colonized by Phœnician merchants; another, by Carthaginians. America was peopled by Carthaginians, says Venegas, and Anahuac is but another name for Anak. Besides, both nations practised picture-writing; both venerated fire and water, wore skins of animals, pierced the ears, ate dogs, drank to excess, telegraphed by means of fires on hills, wore all their finery on going to war, poisoned their arrows, beat drums and shouted in battle. Not an unfair example this of the scientific deductions of the day. Surely he must be unreasonable who refuses to be convinced by such testimony!

Says the pious Cotton Mather, the natives of the country now possessed by the New Englanders had been forlorn and wretched heathen ever since they first herded here, and though we know not when or how these Indians first became inhabitants of this mighty continent, yet we may guess that probably the devil decoyed those miserable savages hither, in hopes that the Gospel would never come here to disturb his absolute empire over them.

The evidences that the Indians came from Scandinavia are as convincingly put as those proving that they came from Ireland, or Iceland, or Greenland. Equally conclusive are the arguments for a passage by the Indian across Bering Strait from Asia, across the Northern Pacific from Japan or China in junks, or across the Southern Pacific in canoes from the Polynesian Islands, or Australia. Even Africa is not too far distant to send its contingent to the new land; and when the ocean has been deemed to be too broad to permit a passage from foreign shores the willing imagination of the writer has dropped an island into mid-ocean, and called it Atlantis, to facilitate alike the crossing of the Indian and the reception of a fanciful theory. Thus there is a theory of origin to suit the tastes of all. If you have a special bias or predilection, you have only to choose for yourself. If there be any among you who decline to find the ancestors of our Indians among the Jews, Phœnicians, Scandinavians, Irish, Welsh, Carthaginians, Egyptians, or Tartars, then you still have a choice among the Hindu, Malay, Polynesians, Chinese, or Japanese, or, indeed, amongst almost any other of the children of men.

Preposterous as may seem many of the theories above alluded to, nearly all of them rest upon a certain basis of fact and comparison. Many, at least, of the similarities of thought, custom, methods, arts, religions, and myths from which the theories are deduced indeed exist, though false analogies permeate them all. The thread of fact which sustains the theories is, moreover, far too slender to bear the weight put upon it. It is not that the theories contain so much that is erroneous but the proof offered is entirely insufficient. The science of yesterday reared its edifices upon foundations of fact the very slightest. The science of to-day demands broader foundations and more deeply laid upon which to base its conclusions. Erroneous hypotheses like the above have, however, been productive of great good in pointing out and emphasizing some of the most useful lessons which the student of anthropology of the present day must learn and ever keep in mind. Of these perhaps the most important is that the human mind is everywhere pratically the same; that in a similar state of culture man in groping his way along will ever seek the same or similar means to a desired end. That, granting the same conditions of environment, man acts upon them and is acted upon by them in the same way the world over. Hence, in large part, arise those similarities of customs, beliefs, religions, and arts which have been appealed to as evidences of genetic connection or of common origin, when, in fact, they are evidences of nothing but of a common humanity.

This leads us to speak briefly of some of the leading methods of classification by which men of science have sought to solve the problem of the origin and relation of races, and among other peoples of our own Indians.

The physical tests of race most approved by ethnologists are colour, viz. the colour of the skin, hair, and eyes; the structural differences of the hair; the size and shape of the skull as determined by capacity and measurements; and the test of language.

Few of the tests formerly relied upon in classifying mankind have proved less satisfactory to modern investigators than that of colour. The microscope appears to show that colour is not due to organic differences of race; not only are there great differences in the colour of individuals of the same tribe, but of the same family, and even in the same individual at different periods of life. Thus, in the case of our Indians, it is well known that the skin of the infant at an early age is very light-coloured, scarcely distinguishable, in fact, from a Caucasian child, and that it assumes a deeper shade only with advancing years. This, I believe, is true irrespective of tribe or habitat. The hair of the Indian child is brown instead of black. The colour of the adult Indian varies within very wide limits, but singularly enough he is never copper-coloured or red, as he has been called from the time of the discovery. All our Indians are brown, and while certain tribes, as the Tuscaroras and Mandans, are so light as to give rise to the theory that they are descendants of the Welsh, other tribes, as some of the Californians, are so dark as to closely approach the black Africans. I say black Africans, for it is to be remarked, in passing, that some African tribes are very light-coloured.

The division of mankind into four groups—white, black, copper, and olive—is, in a general way, consistent with facts. Moreover, these divisions are, to a certain extent, correlated with geographical range and climate, and thus correspond to the colour differences of birds and animals. That they are also and perhaps more strictly correlated with culture status is not to be doubted; for it may be said, in a general way, that all civilized peoples are light-coloured and nearly all barbaric and savage peoples are dark-coloured. So complete, however, is the intergradation of colour when all varieties of mankind are considered, and so intangible are the distinctions which must be relied upon to distinguish them in the case of individuals and even of tribes, that it appears that while colour affords a convenient off-hand means of classification, and while it may be made useful in connection with other criteria, it is quite insufficient in itself as a test of race.

The more obvious peculiarities of the hair, according as it is straight, crisped, or curly, early attracted the attention of ethnologists. The modern microscope has shown that these peculiarities are more or less intimately correlated with structural differences, and that the straight hair of the American Indian and the Mongolian is nearly cylindrical in section, while the frizzled hair of the Negro and Papuan shows an oval or flattened section. Between the two extremes, however, are too many shades of difference to permit the extensive use of this criterion as a race classifier, except in a subordinate way.

Much time and thought has been expended by craniologists in the effort to classify races by means of the skull. Notwithstanding the great ingenuity exercised in devising methods and instruments to secure constant results and trustworthy figures as a basis for comparison, the results thus far obtained have been disappointing. So faulty were the mechanical means adopted by the earlier craniologists that students of to-day are compelled to discard their data and resulting conclusions and begin almost *de novo*. There are many able men who are sanguine not only that the physical structure of man may yet be made to reveal secrets bearing upon the origin of races, if there be more than one, but that the science of craniology in particular is destined to have an important bearing upon these racial problems. Whatever the future of craniology or the other methods of classification by physical characteristics may have in store, the contradictory results thus far obtained offer little to satisfy us. Not only do the naturalists and ethnologists who have studied man's physical characteristics differ as to the number of races of mankind, and as to what constitutes a proper basis for classifying them, but thus far there has been little agreement as to the assignment of particular tribes or peoples. Perhaps more authorities are agreed that there is but one race and one origin of mankind than agree upon any greater specific number; but when it is remembered that there are authorities who place the number of distinct races at two, three, four, five, six, seven, eight, eleven, sixteen, and that one places the total as high as sixty-three, it will be agreed, I think, that it is better to suspend judgment and not to accept any present result as final.

We have already noted that the earlier theories of origin for the Indian, based as they largely were upon certain assumed analogies of customs, laws, religious observances, myths, &c., rested upon such slight foundations as to hardly entitle them to be classed as scientific hypotheses. We have also seen that up to the present time the attempts to classify mankind by his physical characters have produced discordant results, and that little dependence is to be placed upon the results themselves or upon the theories arising therefrom which relate to the more profound question of the origin of races. In turning to the test of language, if doubt and uncertainty were left behind and harmony and agreement took the place of discordant views we might count ourselves fortunate indeed. But such is not the case. We have indeed only to go back a short time to find that the generalizations drawn from the study of language are as crude, the hypotheses as baseless, the theories as wild as are those we have just glanced at. Nor is this strange. Like its sister sciences, linguistics had to pass through a period in which speculation and hypothesis, instead of going hand-in-hand with facts and induction, usurped their place. Until the inductive method was born no science of philology was possible. The science of comparative philology is indeed of recent origin, nothing worthy of the name existing before the present century. Within the last fifty years it has made a wonderful growth and achieved results little short of marvellous. Though still in its infancy as regards future possibilities, and while it needs and welcomes the aid of all the other sciences to solve the complex questions which come properly within its domain, it is unquestionably our best guide in problems relating to the origin and relationship of the races of mankind. . . .

No part of the known world affords a better opportunity for the study of the nature of language and its processes of growth than America. The Indian languages are by no means the most primitive at present spoken by man, and it may surprise some of my hearers to be told that in respect of some of their characteristics they compare favourably with Greek and other classic tongues, though the classic languages as a whole belong to a much higher stage of development. Instead of being mere jargons of words, disconnected with each other and capable of expressing only the simplest ideas, as I find many intelligent people believe, they are in some directions singularly highly developed, and not only are they capable of serving as the vehicle of every thought possible to their possessors, but their vocabularies are extensive, possess many synonyms, and furnish the means of discriminating the nicest shades of meaning.

There is not a principle or process in the most highly developed languages of which the germs at least are not discernible in Indian languages. The differences are not those of kind but of degree of culture.

Moreover inherent in them is the power of unlimited growth and expansion, and just as our own language grows, keeping step with advances in science and art, so Indian languages are capable of a development equal to the most exacting demands of civilization.

While thus in many respects highly developed, Indian languages are not to be compared as vehicles of thought with such languages as our own English, for instance. As a body they are still in that stage of development in which the various processes of language-making may be studied with comparative ease. Just as the various natural processes by which mountains are levelled and the earth's surface carved out and remodelled are more apparent and more readily studied by the geologist in the still primitive West, so Indian languages offer to the scrutiny of the linguistic student a similar unfinished condition highly favourable for analysis and study.

For the past fifteen years Major Powell and his assistants of the Bureau of Ethnology, with the aid of many collaborators in various parts of the country, have been accumulating vocabularies by means of which to classify Indian languages. The present provisional results of the study of the large amount of material accumulated appear before you on the Linguistic Map, which is coloured to show the areas occupied by the several linguistic families. Of these there appear no fewer than fifty-eight.

What interpretation are we to place upon the astonishing fact that in the territory north of Mexico there were at the time of the discovery fifty-eight distinct Indian linguistic families, containing some 300 or more languages and dialects?

So far as Language is a competent witness, she has exhausted all the evidence thus far accumulated when she has grouped the Indians in fifty-eight families. Back of this point she may not now go except as a theorist and in pure speculation. So far as she is entitled to speak authoritatively, these fifty-eight families are separate entities, which never had any connection with each other. But she recognizes her own limitations too well to dare to state positively that this is the interpretation that must be placed upon the results she has attained. When facts from which to draw deductions fail, men may and do resort to theories. Let us glance at the two broad hypotheses which have been based upon the development theory of language. The first is in effect that all the present languages of the earth are not so unlike that they may not have been developed from a single original parent language. By this view the original language is supposed to have changed and developed into all the various forms of speech that are now spoken or that have ever been spoken. According to this view the families of languages as at present classified have no other significance than as groups of related tongues, the once existing connection of which with other tongues cannot now be proved, because through the process of change the connecting links have been lost.

The second hypothesis assumes that there must have been at least as many original languages as there are now existing families; it assumes, in other words, that the families of speech are fundamentally distinct and therefore cannot have had a common origin. The first theory postulates that from original unity of language has come infinite diversity; the second that the tendency has ever been from original diversity towards unity.

Widely different as are these two theories of the origin of linguistic families, they agree in one essential particular. They both remove the origin so far back in time as to make it practically impossible to *prove* the truth or falsity of either theory.

Both of these hypotheses have able advocates; but for a variety of reasons, which time will not permit me to give, the second is deemed the more plausible. At all events, it best explains many difficulties.

There is abundance of archæologic evidence showing that man has resided on this continent for a very long period, and the character of the remains proves that the farther back in time we go the ruder being he was. Linguistic testimony is to the same effect, and there is no *a priori* reason why man may not have lived upon this continent ages before he learned to talk—no reason, for that matter, why America may not have peopled the earth, if the earth was peopled from a single centre, or why, if there have been several centres of origin for mankind, the Indians, as they themselves believe, may not have originated here where they were found.

It is the fashion, I hardly know why, unless it be the religious bias, for those who hold that language has had but one origin to assume that America is the younger continent, so far as her people are concerned, and to infer that it was peopled from Asia. If America was peopled from Asia in modern times, there should be some evidence of the fact in American languages. But there is no evidence of the sort. None of the American families of language are in any way related to the Asiatic tongues. Bering Strait furnishes, indeed, a perfectly practicable canoe route from Asia to America, but it appears to have been generally overlooked that the Strait furnishes an equally accessible route from America to Asia. The latter is demonstrated by the fact that the Eskimo of Alaska have in recent times sent an Eskimo speaking colony across Bering Strait to Siberia. In other words, so far as direct testimony goes, Asia is indebted to America for a small segment of its people, but America owes no similar debt to Asia. With reference to the origin of our Indian tribes, then, linguistic science is in a position to state this much, that if our Indians came to America, either from Asia or from any other foreign shore, it was at a period so remote as to permit such profound changes in the structure of the language brought here by the immigrants that no traces of genetic connection are now discernible.

If we reject the one origin theory of language, and assume that each linguistic family originated independently, there is obviously not the slightest use of turning to Asia or Europe for anything like a recent importation of the Indian; for have we not fifty-eight distinct origins to account for? Obviously the fifty-eight families are as likely to have originated here as anywhere else; for remember that every country has linguistic families of its own to account for. Is there, then, any possible theory which will meet the case? There is certainly one that is possible, if not probable. It is the theory that, whether born from the soil or an immigrant from other lands, our Indians spread over the entire continent before they acquired organized language, and that from not one but from fifty-eight centres sprang up the germs of speech which have resulted in the different families of language. This theory accords with the idea that there may have been but one origin of man, and that in any event all the Indians from the Arctic to Patagonia are of one race. It does not forbid the supposition that the Indian was an immigrant from other shores, though it permits the thought that the American Indian may have originated on American soil.

Though this theory seems more probable than the other, which assumes that the languages of our Indians were brought here from foreign shores, it must be frankly admitted that linguistic science is not now and possibly never will be competent to decide between them. If she is unable to decide fully as to the origin of the Indians' languages, how can she be expected to solve the infinitely more complex problem which concerns the ultimate origin of the peoples who spoke them? She certainly has no solution for this problem now. When she considers the number of linguistic families, and the vast length of time it must have taken to develop their languages and dialects, she finds herself confronted by a problem beyond her present powers. And yet the case is not hopeless. Linguistic science is still in its infancy, and its future may contain possibilities far exceeding the dream of the most sanguine. As science has revolutionized the world's processes, and has made the impossibilities of a hundred years ago the common-places of to-day, so like wonders may be achieved in the domain of thought, and the science of Language, with the assistance of her sister sciences, may yet answer the unanswerable questions of the present. . . .

When interrogated as to the origin of the Indian, all that she can now say is that, whether the Indian originated on this continent, where he was found, or elsewhere, it was in bygone ages—ages so far removed from our own time that the interval is to be reckoned, not by the years of chronology, but by the epochs of geologic time; with such problems she affirms that at present she cannot deal.

THE NEW OBSERVATORY IN CATANIA.

WE learn from the *Corriere di Palermo* the following details concerning the new Observatory at Catania, in which active work is about to begin. For many years astronomical studies were carried on with success in the Observatory at Palermo, but owing to the great drawbacks arising from the position of this institution (amongst which the most serious was the close proximity of a railway), it became exceedingly difficult to make precise observations. Some of the astronomers of the Observatory preferred to devote themselves to researches in astronomical physics, in which the inconveniences were less felt, while others who continued to occupy themselves with astronomy of position had to contend against ever-increasing difficulties. The Government, being informed of the state of affairs, nominated in 1888 a Commission to select a more suitable spot, and to make arrangements for a new Observatory; and the only place found suitable was the mountain Consuono, near Bagheria. As an Observatory built there would have the most perfect conditions of quiet and stability, it was decided that it should be devoted to the ancient and classical branch of astronomy of position.

In the meantime, several years ago, a new Observatory had been built on Etna (at a height of 3000 metres), through the activity of Prof. Tacchini, and the approval and help which the project found in Catania. Prof. Tacchini, recognizing the necessity that the Observatory at Etna should be joined with another, that it might work with greater regularity, succeeded in inducing the Government to build and organize the Observatory connected with the University in the town of Catania. This institution is destined principally for the study of astronomical physics, for celestial photography, for meteorology, and for seismology. Direct astronomical and spectroscopical observations will be made for the most part in the upper story of the Observatory with the great refractor, which has an objective of 35 centimetres in aperture and 5⅓ metres in focal length. It was made by the celebrated Merz at Munich, and the equatorial mounting was executed by the able mechanician Cavignato, of Padua, under the direction of the astronomers Lorenzoni and Abbeti, of that town. Other observations will be made with the equatorial of 15 centimetres in aperture, constructed by the renowned American, Clarke, to which an apparatus can be added for the photographing of stellar spectra. This instrument will be placed in the garden of the Observatory, liberally given by the Municipality of Catania.

In the same place, in a suitable pavilion, will be fixed the photographic telescope, with an objective of 33 centimetres in aperture. This was constructed by Steinheil, and the mounting was made under the direction of Prof. Tacchini in the premises of the clever mechanical engineer, Salmsiraghi, at Milan. With this instrument the Observatory at Catania will take part in the great international enterprise of preparing photographic charts of the stars. In the same garden the apparatus of Huggins will be set up, which serves for the photographing of the solar corona. Besides, at the Observatory on Etna, there is an equatorial, equal to that of the great refractor; and to this it will be possible to apply the same objective of Merz, and another which, for special observations, astronomical and physical, will be taken to the volcano.

Observations in meteorology will be made, some in the upper story of the building, where the apparatus of Mascart for the photographic registration of atmospherical electricity will be worked. Other meteorological observations will be made in the garden; and the Observatory on Etna will be furnished with a collection of meteorological and seismological instruments capable of automatic registration at times when the Observatory will be inaccessible. The seismological instruments will be by degrees removed from the University of Catania, where they are now collected, to a far more suitable place—to the vast subterranean rooms of the Observatory; thus, in the network of stations, this institution will take the first place for the seismological service of Sicily and the adjacent islands.

Prof. Riccò has been appointed regular Professor of Astronomical Physics in the University of Catania, and Director of the two Observatories. He is a member of the International Committee for photographing the stars.

NOTES FROM THE OTAGO UNIVERSITY MUSEUM.

X.—THREE SUGGESTIONS IN BIOLOGICAL TERMINOLOGY.

(1) MR. R. J. HARVEY GIBSON has recently criticized my proposal to use the terms *gamobium* and *blastobium* for the sexual and asexual generations respectively in both plants and animals, and has given some very good reasons for objecting to the latter term.[1] I therefore propose to replace it by *agamobium*, using the word simply as a monomial equivalent of "asexual generation," *gamobium* being similarly employed for the sexual generation. Both terms are equally applicable to plants and animals, and to the various kinds of alternation of generations.

(2) Mr. Gibson, while using the word *ovarium* for the female gonad or ovum-producing organ both in plants and animals, objects to my employment of the anglicized form of it (ovary), because of the confusion arising from the fact that the name is applied to something quite different in Angiosperms. My own impression is that reforms of this kind should be thorough, and that, if it is once admitted that terms of fundamental importance should not be used in one sense for animal and in a totally different sense for vegetable organisms, it would be the ruin of the whole scheme to be obliged to describe the ovarium of an Angiosperm as something contained within an ovule, which is itself enclosed in an ovary. We have already the accurate word megasporangium for the ovule, and I propose to speak of the so-called ovary, by a purely descriptive term, as the *venter* of the pistil.

(3) Every zoologist must acknowledge the services rendered by Haeckel and others in giving names to the more important embryonic stages of animals. It appears to me desirable that the equally important stages in plant development should be similarly emphasized.

In the paper already referred to I have proposed that the one-celled embryo, *i.e.* the immediate product of the conjugation of ovum and sperm should be universally called the *oosperm*, the objectionable name oospore being dropped.[2]

In mosses and vascular plants, as in animals, the next stage of importance after the oosperm is that in which the embryo consists of a mass of undifferentiated or but slightly differentiated cells. It is a matter of minor importance that in some cases a long axis is already obvious, or that in others an apical cell is formed: the stage may be conveniently distinguished by Lan-

[1] See Gibson, Proc. Biol. Soc. Liverpool, vol. iv. (1889) p. 24; *ibid.*, 1887; and Parker, Proc. Austr. Assoc. Adv. Sci., vol. i. (1888).

[2] May I venture to protest against the extended use of the word oosperm sanctioned by my friend Prof. Haddon, who, in his excellent "Embryology," uses it (p. 91) for an advanced mammalian embryo with membranes?

kester's name *polyplast*, which is to be preferred to Haeckel's *morula*.

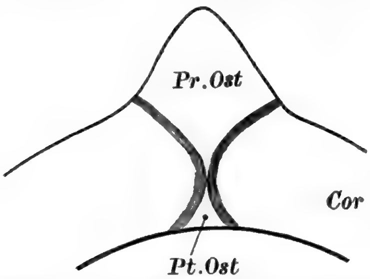
In mosses, the agamobium never gets beyond this stage, the fully formed sporogonium being nothing more than a highly differentiated polyplast. But as in animals the polyplast is succeeded by a gastrula, *i.e.* a stage in which the characteristic organ of animal nutrition has appeared, so in vascular plants it is succeeded by a stage in which the characteristic organs of plant nutrition—the leaf and root—have made their appearance. From ferns up to Angiosperms the first important differentiation after the polyplast is the formation of a cotyledon and of the primary root. This stage, the obvious correlative of the animal gastrula, I propose to call the *phyllula*.

XI.—ON THE PRESENCE OF A STERNUM IN *Notidanus indicus*.

As far as I am aware, nothing answering to a sternum has hitherto been found in fishes, the Urodela being the lowest group in which this constituent of the skeleton is known. In them it consists of a median plate of cartilage formed from paired chondrites (independent cartilaginous elements) developed in the inscriptiones tendineæ immediately caudad of the coracoids, and in close connection with them. In many Anuræ there is found in addition a median element cephalad of the procoracoids. The entire Amphibian sternum is conveniently called by Albrecht the *omosternum*, to distinguish it from the costal sternum of Amniota; the anterior division (omosternum, W. K. Parker) being called the *pre-omosternum*, the posterior division (xiphisternum, auct.) the *post-omosternum*. According to Wiedersheim ("Grundriss," 2te Aufl., p. 58), the phylogeny of the Amphibian sternum is still entirely unknown.

In Elasmobranchs the shoulder-girdle has the form of an inverted arch, usually formed of a single continuous cartilage, due to the union in the middle ventral line of paired elements, one connected with each pectoral fin. In Hexanchus (Notidanus) the right and left sides are described by Hubrecht ("Bronn's Thierreich," Fische, p. 77) as being united by fibrous tissues.

In a skeleton of *Notidanus indicus*, recently prepared for this Museum, the middle region of the shoulder-girdle has the structure shown in the figure. It is produced in front into a blunt



Median ventral region of the shoulder-girdle of *Notidanus indicus*, ventral aspect (natural size). *Cor.*, coracoid region: *Pr.Ost.*, pre-omosternum; *Pt.Ost.*, post-omosternum.

process, while it is evenly curved posteriorly. Two curved areas of fibrous tissue, with their convexities towards the median plane, extend from the anterior to the posterior border, touching one another in the centre, and thus bounding two distinct cartilaginous areas—an anterior (*Pr. Ost.*) of a rhomboid, and a posterior (*Pt. Ost.*) of a triangular form. The anatomical relations of these seem to show that the former is to be considered as a pre-omosternum, the latter as a post-omosternum.

The specimen in question appears to furnish a very good indication of the phylogeny of the sternum, and to show that it arose in the first instance by the segmentation of a mid-ventral element from the shoulder-girdle, in much the same way as the basi-hyal and basi-branchials are formed from the hyoid and branchial arches. T. JEFFERY PARKER.

Dunedin, N.Z., September.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. M. J. M. Hill, of University College, London, has been approved for the degree of Doctor in Science.

Mr. H. W. Page, M.C., M.B., of Christ's College, has been appointed an additional Examiner in Surgery.

A. H. L. Newstead, B.A., of Christ's College, has been appointed by the Biology Board to occupy the University table in the Laboratory of the Zoological Station at Naples for six months from December 15, 1890.

Mr. J. Y. Buchanan, F.R.S., University Lecturer in Geography, announces a course of lectures in Physical Geography and Climatology for the ensuing Lent and Easter Terms.

The Clothworkers' Exhibition of fifty guineas a year in natural science for non-collegiate students will be awarded next July. Candidates are to apply to the Censor of Non-Collegiate Students.

The General Board of Studies recommend that Mr. R. T. Glazebrook, F.R.S., be appointed Assistant Director of the Cavendish Laboratory. Mr. Glazebrook resigns the Senior Demonstratorship which he has hitherto held.

A very interesting account is published in the *University Reporter* of December 9, 1890, of the course of study in natural science pursued by the University Extension students who were resident in Cambridge during the last Long Vacation. The course included invertebrate palæontology, practical chemistry, and physics. Courses were also given in Greek art, architecture, Egyptology, &c. The Lectures Committee recommend that the experiment be repeated on a larger scale next year.

Additional demonstrators in physiology and in experimental physics are about to be appointed, to be paid out of the laboratory fees of students.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for November 1890 contains:—On the structure of a new genus of Oligochæta (Deodrilus), and on the presence of anal nephridia in Acanthodrilus, by Frank E. Beddard (plates xxxii. and xxxiii.). This large worm, *Deodrilus jacksoni*, measuring thirteen inches in length by nearly half an inch in diameter at the broadest part, was collected by Prof. Moseley in Ceylon; the nephridia in a species believed to be *Acanthodrilus multiporus* are described as connected with the terminal region of the intestine.—Excretory tubules in *Amphioxus lanceolatus*, by F. Ernest Weiss (plates xxxiv. and xxxv.). At the Zoological Station in Naples, the author was able to have a constant and unlimited supply of Amphioxus, and he took the opportunity of experimenting with the view of determining whether the curious patches of modified epithelial cells on the ventral wall of the atrium of Amphioxus had any excretory function, as Johannes Muller had held to be probable; and whether, also, the atrio-cœlomic funnels, first described by Prof. Ray Lankester, had any such function; positive results were not obtained.—Studies in mammalian embryology; ii. The development of the germinal layers of *Sorex vulgaris*, by Prof. A. W. Hubrecht (plates xxxvi. to xlii.). Giving a brief but very lucid sketch of the various views held by recent writers concerning the gastrulation process of the Amniota and the formation of their mesoblast and notochord, placing what is agreed on on the one side, and indicating the points of difference on the other, without any polemical remarks, the author proceeds to an account of the early developmental stages of Sorex, the blastula and the didermic blastocyst, the development of the mesoblast; then follow some theoretical considerations on the gastrulation of the Mammalia, concluding with points of comparison in earlier investigations by other authors.—Terminations of nerves in the nuclei of the epithelial cells of tortoise-shell, by Dr. J. B. Haycraft (plate xliii.). The scutes of the land tortoise (*Testudo græca*), in spite of their hard, dense nature, form a very typical epidermic sensory covering for the animal. As in the soft skin of mammals, the nerves end in localized sensitive spots in the epidermis, and before penetrating this tissue they form a horizontal plexus in the upper part of the connective tissue; figures of the nerve-endings are given.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 27.—"The Variations of Electromotive Force of Cells consisting of certain Metals, Platinum, and Nitric Acid." By G. J. Burch and V. H. Veley.

The description of the apparatus, the capillary electrometer, and the method of working are given fully in the paper. The following conclusions are drawn from the results of the experiments:—

(1) When the metals copper, silver, bismuth, and mercury are introduced into purified nitric acid of different degrees of concentration, and a couple made of platinum, the electromotive force of such a cell increases considerably from an initial value until it reaches a constant and (in most cases) a maximum value. The rise of E.M.F. is attributed to the production of nitrous acid by the decomposition of the nitric acid, and the final value is considered to be due to the former acid only, while the initial value is due for the most part to the latter acid, though it is affected to a remarkable degree by the amount of impurity of nitrous acid, either initially present or produced by minute and unavoidable uncleanliness of the metallic strip and the containing vessel.

(2) If nitrous acid has been previously added to the nitric acid, then the maximum E.M.F. is reached *at once*.

(3) If the conditions—namely, increase of temperature, of impurity, and of concentration of acid—are such as would favour a more rapid solution of the metal, and consequently a more rapid production of nitrous acid, then the rise of E.M.F. is concomitantly more rapid.

(4) Conversely, if the conditions are unfavourable to the production of nitrous acid, the rise of E.M.F. is less rapid.

(5) If any substance, such as urea, be added which would tend to destroy the nitrous acid as fast as it may be formed, then the rise of E.M.F. is extremely slow, being dependent upon the number of molecular impacts of the nitrous acid upon the surface of the metal.

Thus the results obtained by the electrometer and by the chemical balance are in every way confirmatory the one of the other.

The authors propose to conduct further investigations on cells containing other acids, to determine whether the action of them upon metals is conditioned by the presence of their products of electrolysis.

Geological Society, November 26.—Dr. A. Geikie, F.R.S., President, in the chair.—The appointment of Mr. L. Belinfante as Assistant-Secretary was confirmed.—The following communications were read:—Account of an experimental investigation of the law that limits the action of flowing streams, by R. D. Oldham, Deputy Superintendent of the Geological Survey of India. A discussion followed, in which Dr. Blanford, Mr. Binnie, Mr. Topley, and the President took part.—On the rocks of North Devon, by Dr. Henry Hicks, F.R.S. During a recent visit to North Devon the author obtained evidence which has led him to believe that far too little importance has hitherto been assigned to the results of movements in the earth's crust as affecting the succession of the rocks in that area. The supposed continuous upward succession from the rocks on the shore of the Bristol Channel to those in the neighbourhood of Barnstaple, including, according to some authors, no less than ten groups, and classed into three divisions under the names Lower, Middle, and Upper Devonian, is, the author believes, an erroneous interpretation. The beds, he says, have been greatly plicated and faulted, and consequently several times repeated, and instead of being one continuous series, they occur folded in more or less broken troughs. In the Morte Slates, previously considered unfossiliferous, the author found a *Lingula*, and he believes that these slates are the oldest rocks in the area, and formed the floor upon which the Devonian rocks were deposited unconformably. As the result of movements in the earth's crust, the Morte Slates have been brought to the surface and thrust over much newer rocks, producing a deceptive appearance of overlying the latter conformably. The Morte Slates mark the dividing line between the two main troughs. On the north side in ascending order are the Hangman (or Lynton), Combe Martin Bay, and Ilfracombe Beds, and on the south side the Pickwell Down, Baggy Point, and Pilton Beds. Those on the south side of the Morte Slates are, the author believes, a repetition of the beds on the north side. The palæontological evidence is not antagonistic to this view, for an analysis of the Brachiopoda, the only group of fossils in the beds on the south side, which hitherto have been systematically examined, shows that of the twenty species mentioned by Mr. Davidson and others as occurring in the Pickwell Down, Baggy Point, and Pilton Beds (the so-called Upper Devonian rocks), no less than thirteen have already been found in the Middle or Lower Devonian rocks on the north side of the Morte Slates. Four others are recognized Middle Devonian species in other areas; and the three remaining are either doubtful species or ones which have a great vertical range. These facts show that the so-called Upper Devonian rocks in this area do not contain a distinguishing fauna of any importance; and the stratigraphical evidence is opposed to the view that they are a series of rocks distinct from those on the north side of the Morte Slates, which have been classed as Middle and Lower Devonian. In the discussion which followed the reading of this paper the speakers were Mr. T. Roberts, Mr. Marr, Prof. Seeley, Mr. H. B. Woodward, Rev. H. H. Winwood, Rev. G. F. Whidborne, Mr. Hudleston, Prof. Blake, the President, and the author. The President remarked that, in altering the recognized order of succession of these rocks, the author would have to reckon also with continental stratigraphers and palæontologists. Dr. Hicks had not made as clear as might be the evidence for such thrust-planes and faults as his views of the structure of the ground required. The plications and dislocations in South Devon and Cornwall, although abundant and often very complicated, appeared to the speaker to be on a comparatively small scale; and, although he did not wish to insist that this must be the case in North Devon, he felt that it might be so.—A special general meeting was held at 7.45 p.m., before the ordinary general meeting, at which Mr. J. W. Hulke, F.R.S., was elected Foreign Secretary, and Mr. J. J. H. Teall, F.R.S., was elected a Member of Council.

Zoological Society, December 2.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of November 1890, and called special attention to the acquisition of a specimen of the Cryptoprocta (*Cryptoprocta ferox*) of Madagascar.—A letter was read from M. A. Milne-Edwards, containing an account of the mode in which the typical specimen of Grévy's Zebra had been mounted for the Gallery of the Museum, and pointing out that the mounted specimen has been carefully modelled after the living animal.—A letter was read from Dr. Emin Pasha, dated "Tabora, East Africa, August 16, 1890," containing an expression of his thanks for having been elected a Corresponding Member; and giving some remarks on the Striped Hyena of that district.—Mr. Richard Crawshay read a paper on the Antelopes of Nyassaland, treating especially of those to be met with west of the Lake. Lichtenstein's Hartebeest was stated to be very generally distributed, and seven other Antelopes to be plentiful. The Kudu, Sable Antelope, and Black-tailed Gnu were seldom met with; but exact localities were given where these Antelopes were to be found. In conclusion, the author added that there are at least two other species of small Antelopes found in the hills, which hitherto he had not been able to identify.—Prof. G. B. Howes read a paper on the peculiar mode of the suspension of the viscera in the Australian Batoid fish *Hypnos subnigrum*.—A second communication from Prof. Howes contained notes on the pectoral fin-skeleton of the Batoidea and of the extinct genus *Squaloraia*, which he maintained must be referred to the Chimæroid group.—Mr. G. A. Boulenger read a paper on the presence of pterygoid teeth in a tailless Batrachian (*Pelobates cultripes*), and added remarks on the localization of the teeth on the palate in the Batrachians and Reptiles.—Mr. H. Seebohm read a paper on the Fijian birds of the genus *Merula*, and gave a description of a new species from Viti-Levu, which he proposed to call *Merula layardi*.

EDINBURGH.

Royal Society, December 1.—Sir Douglas Maclagan, President, in the chair.—This was the first meeting of the Society for the present session.—After the delivery of the President's opening address, Prof. Crum Brown read an obituary notice of Prof. Kolbe.—Dr. John Gibson submitted the results of an analytical examination of manganese nodules, made with special reference to the occurrence of the rarer elements. The nodules which he examined were dredged by the *Challenger* in the North Atlantic. Dr. Gibson has detected the presence of twenty-eight elements. Of these, zinc, tellurium, molydenum, vanadium, and thallium have never previously been observed.—Mr. J. Y. Buchanan, F.R.S., read a paper on the occurrence of sulphur in marine muds and nodules, and its bearing on their modes of formation. The sand and mud at the bottom of the sea, at all depths, forms the food of a numerous and important ground-fauna. In the search after their food, the animals are continually passing large quantities of the mud through their bodies. Evidence of this is supplied by the coprolitic structure of all finer muds, which is rendered visible by careful levigation. The effect of trituration of silicates, under distilled water alone, has been shown to result in partial decomposition. When the milling apparatus is situated in the inside of an animal, and is therefore moistened by organic secretion as well as by sea-water, it is well-known that reaction, resulting in the reduction of the sulphates in the water, takes place. If the silicates, which are being triturated and partially decomposed, contain iron and manganese, the sulphides of iron and manganese are produced, and, being rejected by the animal, form a more or less bluish mud. When this mud lies on the surface of the sea bottom, and is exposed to the action of the sea-water, which always contains dissolved oxygen, the sulphides are oxidized, so that the reddish-brown surface layer, so frequently observed, is formed. When the sulphides come into contact with pre-existing higher oxides, such as Fe_2O_3, ferrous oxide is formed, and sulphur is separated. Reasoning on these grounds, Mr. Buchanan concluded that it must be possible to find free sulphur in all marine muds. In blue muds the sulphur is partly pre-existent, and is partly formed on drying in the air. In red clays, and in manganese nodules, it is wholly pre-existent. Examination of twenty-five muds, and of nodules from all regions, comfirmed this view, as they all gave up sulphur on exhaustion with chloroform. Mr. Buchanan made a number of experiments on the reaction of the sulphides of iron and of manganese on the ferric salts and oxide. He found that precipitated MnS acts on solutions of iron salts exactly in the same way as an alkaline sulphide does. It reduces ferric salts, and at once, and completely, precipitates ferrous salts as FeS. The reactions of MnS on ferric hydrates gave interesting indications regarding the probable nature of the "red cherty particles" so frequently observed in manganiferous bottoms. Mr. Buchanan concludes that the ochreous matter, hydrated oxides of iron and manganese, so abundant on the surface of the bed of the ocean, spring from silicates, and other combinations, by reduction to sulphides in a process of digestion and subsequent oxidation by the atmospheric oxygen of the sea-water. They may also be re-reduced and re-oxidized repeatedly.—Dr. John Murray communicated an anatomical description, by Mr. F. E. Beddard, of two new genera of aquatic Oligochætæ.—Mr. John Aitken exhibited and described a pocket form of his dust-counter, intended for meteorological observations. This form of the instrument is much reduced in size, and is greatly simplified in construction.

PARIS.

Academy of Sciences, December 1.—M. Duchartre in the chair.—On the Fourchambault tornado, by M. H. Faye. The author points out, among other things, that it will be extremely interesting to verify M. Dommet-Adamson's assertion that the gyrations took place in the same direction as the hands of a watch. This has also been noticed in some tornados in the United States, but is very rare.—On some new fossil plants observed at Portugal, and indicating the passage from the Jurassic to the Lower Cretaceous formation, by M. G. de Saporta.—Observations of Zona's new comet, made at Algiers Observatory, with the *coudé* equatorial of 0·318 metres aperture, by MM. Trépied, Rambaud, and Renaux. Observations for position were made on November 17, 18, and 20.—On a new method of displacement of a double cone, by M. A. Mannheim.—On the compressibility of mixtures of air and carbon dioxide, by M. Ulysse Lala. The author has experimented upon mixtures containing 11, 19·35, 26·29, 33·33, 40·08, 47·54, and 56·92 per cent. of carbon dioxide. Between the limits of his experimental pressures, viz. 100·38 cm. of mercury, with volume = 1, and 1613·96 with volume = 0·5, the compressibility of mixtures of dry air and carbon dioxide, when the quantity of the latter gas does not exceed about 22 per cent., is contained between those of the two gases used. It was observed that with mixtures richer in carbon dioxide the compressibility increased.—Reflection and refraction by bodies with abnormal dispersion, by M. R. Salvador Bloch.—On a new process for the differentiation of arsenic and antimony metallic mirrors produced on porcelain, by M. G. Denigès.—On an epithelial fibrillous tissue of Annelides, by M. Et. Jourdan.—Influence of acetic acid on gaseous respiratory changes, by M. Alfred Mallèvre.—On a new haemato-alkalimetric method, and on the comparative alkalinity of the blood of the vertebrata, by M. René Drouin. It is shown that if the alkalinity of the serum of the blood of different species of vertebrata be tabulated, the values may be divided into groups following precisely the same order as the zoological affinities, and that the order in which these classes succeed one another is the same as that of the increase of activity of respiration.—On the structure of nervous centres of *Limulus polyphemus*.—On the external differences presented by the *Nematobothrium, a propos* a new species (*N. Guernei*), by M. R. Moniez.—The enterocele nervous system of Echinodermata, by M. L. Cuénot.—Experimental researches on the locomotion of Arthropods, by M. Jean Demoor.—Comparative influence of light and weight on mosses, by M. Eugène Bastit.—On the presence of lactifers in Fumariaces, by M. L. J. Léger.—Principal indices of refraction of anorthite, by MM. A. Michel Lévy and A. Lacroix.—On the tempest of November 23 and 24, 1890, and the vertical movements of the atmosphere, by M. Alfred Angot.

STOCKHOLM.

Royal Academy of Sciences, November 12.—On the spectrum of absorption of brome, by Prof. Hasselberg.—Determinations of the longitude between the Observatories of Stockholm, Copenhagen, and Christiania, executed by C. F. Fearnley, F. C. Schjellerup, and D. G. Lindhagen.—On the recently executed expedition to Spitzbergen, conducted by G. Nordenskiöld, and its scientific results, by Baron Nordenskiöld.—On the results of the latest Swedish hydrographic expedition in Skagerack and Kattegat during the winter 1890, by Prof. O. Pettersson.—On floating pumices and slags stranded on the shores of North Europe, by Hr. H. Bäckström.—Mineralogical notes, iii., by Hr. G. Flink.—On the employment of infinite determinants in the theory of linear, homogeneous, differential equations, ii., by Hr. H. von Koch.—On a single case of permanent movement with rotation, by Hr. E. Phragmén.—On the waterspout at Wimmerby, July 4, 1890, by Hr. T. Wigert.—On the oxidation of phenyl-methyl-triazol-carbon acid, ii. Phenyl-triazol-dicarbon acid; *a*. The constitution of phenyl-triazol-carbon acid, by Dr. Bladin.—On the constitution of the cummenyl-propion acid, by Prof. Widman.—On the shifting from propyl to isopropyl in the cumin series of the latter, by Prof. Widman.—A review of the mosses of Småland, by Hr. R. Tolf.—Researches on the soft parts of the supernumerary radii of the hand and the foot, by Miss A. Carlsson.

THURSDAY, DECEMBER 18, 1890.

SHAKING THE FOUNDATIONS OF SCIENCE.

DURING the past twenty years there has been gathered together round the site of the 1862 International Exhibition a national collection of museums and schools for instructing the people in art, natural history, and in pure and applied science. For a time a senseless howl was raised that the whole thing was a mighty job to benefit a few, and the antagonism reached its climax when it was proposed to celebrate the year of the Queen's Jubilee by erecting the Imperial Institute on the "inaccessible" spot at which so many millions from all parts of London—nay, from all parts of Great Britain—had congregated to study fishes and food, microbes and music, inventions and instantaneous illuminations, the colonies and coloured fountains.

At length the more sensible of the critics began to realize that the supposed sinecurists at South Kensington were enthusiastic workers who, had they devoted their intellectual powers to the common occupation of enlarging their balance at the bankers instead of to the uncommon occupation of enlarging our knowledge of Nature, would have become capitalists whose vested interests would have been deemed more sacred than life or honour. As it is, the hosts of Mammon now threaten the domain of science in Exhibition Road, for it is actually proposed to make an underground railway, with trains running at frequent intervals, right under Prof. Rücker's laboratory, right under Prof. Norman Lockyer's observatory, and skirting the electrical research laboratories of the City and Guilds Technical College, called the Central Institution.

The English nation (for what concerns the development of our science concerns the nation at large) must abandon its oft-boasted claim of being a practical people. Germany will laugh us to scorn, France will hit us with an epigram, and Italy will view us with polite amazement. To the Royal College of Science come from all parts of our country science teachers to be taught; to the Central Institution come, in addition to English lads, graduates from colleges in Europe and America to learn how England teaches the application of science to industry. Shall they come to find a rumbling earthquake led from early morn to late at night close to the foundations of the very pillars that have been erected at considerable cost in order to secure for the instruments placed on them freedom from even the vibration caused by passing footsteps? On concrete foundations, some 13 feet below the level of the street, rest many pillars of 9 feet square, each quite separate from its neighbour and from the floor on which the students stand; and the upper portion of each pillar is stuffed with a thick cushion of wool, so that the instrument resting on it may give as unwavering a decision as does the Lord Chancellor on the woolsack.

And even this is not sufficient to secure all the quiet that Urania loves, for, just as earthquakes are foretold by the fluttering of the wings of birds, so the approach of a cart at the other end of Exhibition Road is foreshadowed, long before it can be heard, by the uneasy trembling of the very delicate galvanometer needles. Hence must Urania's attendants, the students engaged in research, worship at her shrine by night; and woe betide them if they happen to assemble when a "small and early" is held in Exhibition Road; for then must they cover their heads and mournfully depart, persecuted by the rolling brougham, heartbroken by the rumbling growler, and driven to despair by the rattling hansom. Even at the Cavendish Laboratory, in a quiet back street in the peaceful University town of Cambridge, Lord Rayleigh's most accurate work on the electric units had to be done at night; and Wheatstone's galvanometer magnetic needles at King's College followed the penny iron steamers during the day rather than the electric currents he was measuring.

Judge, then, what will be the effect of passing trains, even though they be drawn by no

> "Kittle of steäm,
> Huzzin' and maäzin' the blessed ground with the Divil's oän teäm,"

on the telescopes in Exhibition Road, which, besides other work, by long-exposure photographs have discovered for us new stars never yet seen in telescope by human eye; or on the galvanometers, whose ray of light aids all electrical industries by pointing out electric flaws in glass and porcelain which the microscope would mistakenly pronounce perfect.

England has just given the Rumford Medal to Prof. Hertz, of Bonn, for his splendid work on electro-magnetic radiation. Will England allow the short-sighted policy of Mammon—

> "Mammon the least erected spirit that fell from heaven"—

to prevent Prof. Boys continuing his work on the same subject at South Kensington? We honour Cavendish for weighing the earth: and now, when Boys has discovered how to hang bodies (not human) by quartz fibres, and so to weigh the earth with far greater accuracy than Cavendish could have done had his attracting balls been the size of houses, shall Boys be prevented from using his own apparatus? Shall the analysis of alternate-current waves at the Central Institution be interfered with by other waves set up by the new burrowing earthworm? We can hardly think so, when we remember how even a dear old soul has just received the news that an underground railway is to run close against our national science schools and laboratories. She, like Huxley's chum Gallio, cares for none of these things, but she had the sense to observe promptly, "Why, it will make all the things wriggle inside."

To study one set of vibrations in the laboratories in Exhibition Road, when another disturbing set is superimposed by the vibration of the building itself, will be like listening to a violin solo when a brass band is braying in the neighbourhood. A prince, the Duke of Edinburgh, renowned for his musical skill, and distinguished as a violin-player at the Albert Hall close by, might fitly take the lead in jealously preserving the possibility for scientific research, the importance of which his father would have been the first to recognize. Urania's voice is like Cordelia's, "ever soft, gentle, and low," and catch it the student never can if his beams of light when moving across his galvanometer and electrometer scales begin

> "To trip it as they go
> On the light fantastic toe."

Radio-micrometers, magnetometers, and every other meter the motion of whose index must be greatly magnified, will become simply museum specimens, illustrating the blindly commercial enterprise of Englishmen, who removed from Trafalgar Square the statue of Jenner, because he only showed us how to save countless lives in every country, and was not distinguished, like the people whose statues remain, by killing many to add to England's landed estate. The 3-foot telescope now being erected in Exhibition Road, will, of course, become useless when the earth-shaking train goes whirling underneath it. Why not leave it at once, like a broken monumental column, to mark the spot where lies buried many a noble hope?

But those who know, from past experience, how "great effects from little causes spring," already ask whether the scientific education of many, and the carrying on of scientific researches, such as have already been conducted in the laboratories in Exhibition Road, may not be worth more to the nation than any number of twopenny-ha'penny railway fares.

And others, whose only claim to be heard is the possession of that rarest of all senses—common sense—ask, Can it be possible that the nation, after having spent such vast sums on the erection and equipment of these laboratories, will now permit them to be rendered well nigh useless?

To move the laboratories of applied science is as undesirable as it is now impossible. Lord Carlingford, at their opening, congratulated the nation that a site had been selected for them close to the Museums, and stated that the French had even just moved the École Centrale of Paris, so that it might be placed in close proximity to the Conservatoire des Arts et Métiers. It is not likely that we shall now reverse our policy, divorce our Schools from our Museums, and, in securing such a result, waste all that has already been spent. If a railway is needed between South Kensington and Tyburnia, let it go under Queen's Gate, and not "Round by the Serpentine under the trees," as sung Lord Algernon. The Muse utters a cry of distress, let us join with her in shouting—

"Procul, oh! procul, este profani."

THE PALÆOZOIC FISHES OF NORTH AMERICA.

The Palæozoic Fishes of North America. By John Strong Newberry. (Monograph of the United States Geological Survey, No. XVI., dated 1889, issued August 1890.) Pp. 228, Pls. liii. (Washington: Government Printing Office.)

NEARLY all of importance that has hitherto been written concerning the Palæozoic fishes of the United States has proceeded from the pen of Prof. J. S. Newberry, of Columbia College, New York, whose numerous contributions during the last thirty years are to be found both in the American journals and periodicals, and in the beautifully illustrated volumes of a few of the State Surveys. Some of these contributions form extensive memoirs and are accompanied by numerous figures; but many are scattered notices without adequate illustration, relating to subjects worthy of much more elaborate treatment. The newly organized United States Geological Survey thus did good service to palæichthyology when it undertook, some time ago, to publish an extended monograph summarizing the whole of Dr. Newberry's researches and bringing them up to date. The result of the undertaking is the fine quarto volume now before us, which not only deals with forms already described, but also makes known a large amount of valuable new material, which the author has assiduously collected from various sources, and, for the most part, added to the unique collection in the Columbia College Museum.

The monograph occupies 228 pages, printed in the Survey's usual excellent style; and there are 53 plates, of which, unfortunately, little complimentary can be said. Eight of the latter are inferior process-reproductions of plates that have already appeared elsewhere, and many of the others are so carelessly produced by the same photographic method, that they give a very imperfect idea of the fossils they are supposed to represent.

Dr. Newberry treats the subject in stratigraphical order, and deals almost exclusively with the fishes of the Devonian and Carboniferous periods. Two pages only are devoted to the recent discovery of Upper Silurian fishes by Prof. Claypole; and no reference whatever is made to the few interesting Palæozoic types briefly described some years ago by Prof. Cope, from the Permian of Texas. The information concerning Devonian and Carboniferous genera, however, is most copious, accompanied by numerous references to literature; and we can only regret that the author did not continue his researches further into taxonomy, thus arranging the forms of each great period in some definite zoological order.

The limits of the Devonian age adopted by Dr. Newberry are somewhat different from those accepted by most American authors, and we doubt whether the inclusion of the Chemung and Catskill groups in the Carboniferous series will be generally accepted by either American or European geologists. The fish-fauna of each of these groups is certainly not Carboniferous, as ordinarily understood. Dr. Newberry considers that the Devonian series in the United States consists of the Oriskany (Lower), Corniferous (Middle), and Hamilton (Upper) groups; and the only fish-remains worthy of description are those from the two latter horizons. The account of the Corniferous fishes occupies 24 pages, and comprises little that is new, being almost exclusively a verbatim reprint from the Ohio Survey Reports of 1873 and 1875. A plate, illustrating several of the bones of the problematical Ganoid *Onychodus*, is the most important addition; and the remarks on the armoured fish *Macropetalichthys* constitute the most serious error that modern researches ought by this time to have eradicated. The fishes of the Hamilton group include more novelties, among which may be specially noted the triturating dental pavement apparently of an Elasmobranch (*Goniodus*), in addition to a new type of ribbed Ichthyodorulite (*Heteracanthus*), resembling in shape the well-known Carboniferous *Physonemus*.

The Chemung, Catskill, and Waverly groups constitute the Lower Carboniferous in Dr. Newberry's classification; and the series of limestones that contain the same fish-fauna as the lowest beds of the British Mountain Limestone are termed Middle Carboniferous. Indeed, looking at the subject from the point of view of physical geology, Dr. Newberry adopts a well-known principle, and also assigns the whole of the Carboniferous Limestone of Western Europe to the middle portion of the Carboniferous epoch, considering that this great division of time terminates with the upper limit of the Permian. The fishes of the Chemung and Catskill groups comprise, among others, the genera *Palædaphus* (*Heliodus*), *Phyllolepis*, *Bothriolepis*, *Onychodus*, *Holoptychius*, and *Glyptopomus*, all of which are essentially characteristic of the Old Red Sandstone and Devonian of Europe, and are never found in the lowest mechanical sediments of the Carboniferous system even in Scotland; while the remarkable new genus *Holonema* is more suggestive of a Devonian Coccostean than of any later type. The fishes of the Waverly group, on the other hand, agree in general character with those of the Calciferous Sandstone and Carboniferous Limestone series of Scotland, except in one particular—namely, the occurrence in certain American horizons of the remarkable gigantic "Placoderms," to which Dr. Newberry has given the names of *Dinichthys*, *Titanichthys*, *Trachosteus*, *Glyptaspis*, &c.

The detailed descriptions of these genera constitute the most important part of the present volume, and add most materially to existing knowledge of the subject. *Dinichthys* is essentially a huge *Coccosteus*, often with jaws two feet in length. *Titanichthys* is a still more gigantic fish, the head sometimes measuring four feet across, and the long, slender, toothless jaws were apparently provided during life with a horny sheath. Some of the remaining genera are also noteworthy for the elaborate ornamentation of their armour; while at least one other (*Mylostoma*) has loose dental plates very suggestive of those of certain Chimæroids and Dipnoi. The series of *Dinichthys* and its allies in the Museum of Columbia College is, indeed, one of the most remarkable exhibitions to be seen in the institutions of the United States, and deserves the closest attention of all interested in the earliest types of fish life.

A contemporaneous Elasmobranch, occurring in the same formation as *Dinichthys*, is also a most striking addition to the Palæozoic fauna; but it is not described, and only forms the subject of two unsatisfactory plates. The dentition is Cladodont, and the species is named *Cladodus fyleri*, while the anterior half of an allied fish is both described and figured under the name of *Cladodus kepleri*. This form of Elasmobranch has small pectoral fins, with an abbreviated basipterygium, and the cartilaginous rays all extending to the outer border; the tail is attenuated, diphycercal, with a pair of horizontal dermal expansions at its base; there are apparently no dorsal fin-spines; and the orbit is surrounded by a complete ring of four ornamented dermal plates. The fish is altogether different from any hitherto found in Europe provided with *Cladodus*-shaped teeth, and increases the already considerable difficulties surrounding the classification of the predaceous Palæozoic sharks.

The discovery of an undoubted *Rhizodus* in the Carboniferous Limestone of Illinois is another fact of some interest; though in this case, as in several others, the author unfortunately omits to mention that the fossil has already been described, without figure, in the publications of the New York Academy. Several fossil teeth and spines of Elasmobranchs are also discussed from the same formation; and the final section of the work is a brief summary of the fishes of the American Coal-measures, accompanied by a reprint of the author's memoir on *Edestus*, which appeared in the Annals of the New York Academy in 1888. The last-mentioned fossil is still problematical, but is considered to be most nearly paralleled by the group of spines met with upon the tail of the existing *Trygon*.

Dr. Newberry's researches have excited so much interest among geologists residing in the neighbourhood of Palæozoic formations in the United States, that Columbia College is the destination of nearly all new discoveries of Palæozoic fishes from every quarter. So much has thus accumulated since the completion of the manuscript for the present monograph, that we understand the author contemplates the issue of an extensive supplement. That such an additional contribution may soon appear will be the wish of all naturalists interested in this line of research.

A. S. W.

HAND-BOOK FOR MECHANICAL ENGINEERS.

Hand-book for Mechanical Engineers. By Prof. Henry Adams, M.Inst.C.E. (London and New York: E. and F. N. Spon, 1890.)

THIS useful book is practically a new and improved edition of Prof. Adams's previous work, "Notes in Mechanical Engineering" The older work has been recast, and much additional matter added to render it of more use to mechanical engineers and to raise it above the level of the ordinary text book. The author rightly observes that busy men must have facts and opinions put before them as briefly as possible, and this is his reason for condensing the information in the book to a compact yet clear form. The work is sure to be an acceptable one to mechanical engineers. The information has in most cases been taken from trustworthy sources, and these are duly acknowledged. It is a pity that the index has not been differently arranged, for there is nothing more annoying when picking up a book of this kind in order to obtain some particular formula or information than to find that it is necessary to settle in one's mind what section it is likely to be in, and then have to search down the columns for a likely paragraph. Had the index been an alphabetical one pure and simple, the handiness of the book would have been greatly enhanced. In some few cases it will be observed that data are quoted from amateur engineering papers. These may be perfectly correct; at the same time the "busy man" will probably doubt their value and trustworthiness.

The book covers an extensive field of mechanical engineering, most branches being well treated. Some of the information, however, is antiquated; for instance on p. 27, we are told that wrought iron is used for "rails." We presume railway rails are here meant. It must be very many years since the last iron rails were rolled for that purpose, and it is possible that there are no works left in this country where the old iron plant is in existence. On the same page it is stated that Yorkshire iron from Lowmoor, Bowling and other forges is used for tyres! This also is distinctly wrong. Who in the year 1890 would use iron tyres on railway rolling stock, when Yorkshire iron costs £20 or more a ton, and when steel tyres can be obtained for a fraction of the cost, without even considering the extra mileage obtained from the steel tyres? Prof. Adams tells us in paragraph 65 of the important process of casehardening wrought iron by heating it in contact with prussiate of potash, &c. In the opinion of many, ordinary bones used in the same way give far better results; and another way of obtaining the same result is to use wood charcoal, soda ash and a little lime. These give excellent results and are generally in use by manufacturers of locomotives and the like. Casehardening in many cases may extend to a depth of $\frac{3}{32}$ inch in important details of valve motions; pins and less important parts may do with a casing of $\frac{1}{16}$ inch in depth.

Paragraph 187 deals with cleaning castings, and here the author would put manufacturers "up to wrinkles," which they certainly are not ignorant of! He speaks of "Holes (we presume he means blow holes) stopped with black putty, cement, or lead." This is all very well in its way, but a casting requiring such treatment should be broken up and sent to the scrap heap. In paragraph 358 the author recommends that safety valves for boilers should have flat faces to prevent sticking. This is not the view taken by locomotive engineers. The most satisfactory valve is one with a conical seat fitted with three or four wings to keep it in position. The actual bearing of the valve on its seat should be about $\frac{1}{16}$ inch wide, or difficulty will be experienced in keeping it tight. In paragraph 369 new boilers are said to be tested to twice their working pressure in the best practice. The author must mean with hydraulic pressure, although he does not say so. This is certainly not the case with new locomotive boilers, nor is it to be recommended on any considerations. The bursting pressure required for any particular boiler can be approximately calculated near enough for all practical purposes, and with a suitable factor of safety allowed there is no necessity for this high test pressure on a boiler. To put a test pressure on a boiler much above its working pressure is to subject it to undue and unnecessary strains, and serves no useful purpose. The usual hydraulic test for a new locomotive boiler does not exceed 50 or 60 lbs. per square inch—about the working steam pressure. This is quite sufficient for the detection of bad workmanship, which is mainly the object of the test. The only satisfactory way to test a boiler is to have it periodically thoroughly inspected by a competent man. The mere testing a boiler with hydraulic pressure is no guarantee that the boiler is fit for work.

Paragraph 398, on the tractive force of a locomotive, is interesting. The reader is told that "the mean effective pressure on the piston is commonly assumed to be 85 per cent. of the boiler pressure." This wholly depends on circumstances. The speed of the engine and the cut-off have everything to do with the mean effective pressure. A heavy 6-coupled goods engine may occasionally exert a tractive force corresponding to a mean effective pressure of 85 per cent. of the working pressure, when starting a heavy train; but, as the speed increases, the cut-off is regulated by the driver and becomes earlier. With a working pressure of 150 pounds, with such an engine, and a cut-off of 30 per cent., the mean effective pressure becomes about 69 pounds per square inch, or about 46 per cent. of the working pressure. A mean effective pressure of 85 per cent. of the boiler pressure corresponds to a cut-off of approximately 70 per cent. of the stroke, or, in other words, the engine is in full gear. It is necessary to assume the highest possible mean effective pressure when the necessary weight on the driving or coupled wheels is being determined for adhesion, since the adhesive weight is in a fixed proportion to the maximum tractive force exerted; but for the purpose of determining the tractive force of a locomotive under varying conditions of speed and cut-off, the mean effective pressure of the steam in the cylinders will be found to be a varying quantity, as may be seen by studying the excellent paper on locomotives, read by the late Mr. William Stroudley before the Institution of Civil Engineers.

It is not necessary to say anything further on these points. The volume contains a mine of information. The theoretical portion is not unduly burdened with complicated formulæ. Those used are simple, and easily used by those not well up in the higher mathematics. Mechanical engineers have to thank Prof. Adams for putting within their reach a most useful book, clearly and concisely written, nicely printed and well bound, and one that certainly ought to be much used by mechanical engineers and those of the allied professions.

N. J. L.

FOSSIL FLORA OF AUSTRALIA.

On the Coal and Plant-bearing Beds of Palæozoic and Mesozoic Age in Eastern Australia and Tasmania; with Special Reference to the Fossil Flora. By B. O. Feistmantel. Memoirs of the Geological Survey of New South Wales, 1890. (Sydney: Charles Potter, Government Printer.)

THIS work is a translation from the author's older work in the "Palæontographica," amended to 1887, edited by R. Etheridge, Jun., Government Palæontologist, and with notes by the Geological Surveyor-in-charge. The greatest development of the older beds occurs in New South Wales, where the coals, sandstones, and shales with plant impressions, are intercalated with porphyries to the thickness of 14,000 feet. Two remarkable facts give special interest to the beds: one is that under beds with Conularia, Spirifer, and Productus, believed to be Upper Carboniferous, certain plants of Mesozoic type appear; and the other, that just under these plant beds there are conglomerates regarded as having been deposited by the action of ice. The formations in New South Wales, Queensland, Victoria, and Tasmania, are described separately, but together they form a series; commencing with the Devonian Goonoo Goonoo, containing Lepidodendron; the Lower Carboniferous Lepidodendron beds; the Boulder beds, showing signs of glacial action, correlated with the similar Dwyka Conglomerate of Africa, and the Talchir Boulder bed of India; the lower marine beds of Upper Carboniferous age, followed by coal measures with Glossopteris, and an upper marine series; the Permian Newcastle beds with Glossopteris and heterocercal fish; the Hawkesbury Trias with

Labyrinthodonts; and lastly some beds of Jurassic age. Until the base of the Upper Carboniferous is reached there is nothing abnormal, but at this point occur the remarkable intercalations of glaciated conglomerates, of which we have some slight indications in our English Permian, and which stretch both to India and Africa. This climatic change killed off the Lepidodendrons, and introduced a new flora containing the wide-spread Glossopteris and its ally Gangamopteris, and Nöggerathiopsis, types which would in Europe appear more at home in the Rhætic than in the Carboniferous, and which followed the changing climate as it spread to other continents. Meanwhile, the Carboniferous fauna of the seas is unaffected, and heterocercal fish accompany plants of quite Jurassic character in the Permian. This mingling of newer land floras with older marine faunas seems so universal in extra-European geology, particularly in America, that it appears as if during period after period the development of marine life was especially forced or quickened in the area which is now Europe, while terrestrial plant life was retarded, especially in England. The genera Glossopteris, Gangamopteris, and Nöggerathiopsis do not extend up beyond the Permian in Australia. In India Glossopteris is rare in the Jurassic, but its recorded extension into the Cretaceous of Russia must be questionable, while its supposed occurrence in the Tertiary of Novale is certainly due to its having been confused with the common Tertiary, and still existing, *Chrysodium aureum*, identical with it in venation but quite different in fruiting. In addition to these, the most noteworthy species are the beautiful adiantoid Rhacopteris of the Lower Carboniferous, to which several plates are devoted, and the Osmunda-like Thinnfeldia of the Mesozoic. The flora of the latter is only remarkable for its very European facies, and is said to include a Jurassic Sequoia, Cunninghamites, Baiera, Walchia, Taxites, and several Cycadeaceæ; it also shares with the Permian the fine *Brachyphyllum australe*, Feistm. There are altogether about 129 species or varieties described, of which about 50 are illustrated, and the volume is certainly a valuable contribution to the history of plant distribution.

J. S. GARDNER.

OUR BOOK SHELF.

The Development of Africa. By Arthur Silva White. (London: George Philip and Son, 1890.)

THERE can be no doubt that Africa is destined to occupy a much more prominent place in the thoughts of Europeans than it has occupied hitherto. The recent marking-off of vast "spheres of influence" may not have very important immediate results, but sooner or later attempts will certainly be made on a great scale to find out in these regions new channels for industry and commerce. It is evident, therefore, that the conditions of the development of Africa ought to be carefully studied; and in the present work, Mr. White supplies all the materials, so far as they are now known, for an adequate comprehension of the subject. He begins with a bird's-eye view of the continent, showing its geological and physical structure, its oceanic and inland drainage-basins, and the coincidence of political settlement with oceanic drainage-areas. Next he deals with the geographical distribution of the chief mountain-systems, and the consequent development of the great river-systems, in relation to accessibility from the sea and internal communications. Under the heading of "climate and cognate phenomena" he treats of the distribution of temperature; actual temperatures; the distribution of atmospheric pressure, and prevailing winds; annual rainfall; distribution of soils; zones of vegetation; distribution of animals; classification of climates; and acclimatization. Then come chapters on the indigenous populations, Islam and Christianity, the traffic in slaves, the progress of exploration, commercial resources, the European domination, and political partition. In the concluding chapter the author presents the general principles underlying the development of Africa along natural lines, derived from an examination of the various aspects under which the continent is known to Europe at the present day. He displays a thorough mastery of the facts relating to the various questions he discusses, and his work will be of genuine service to all who may be for any reason, whether theoretical or practical, interested in the utilization of Africa's material resources. The volume is accompanied by a most valuable series of maps, specially designed by Mr. Ravenstein.

The Pinks of Central Europe. By F. N. Williams, F.L.S. 66 pages, with 2 plates. (London: West, Newman, and Co., 1890.)

THIS forms a third instalment of Mr. Williams's studies of the genus Dianthus. His first paper was devoted to an enumeration and classification of all the known species. In his second he described the pinks of Western Europe, and traced out in detail their synonymy and geographical distribution. In the present paper he deals in a similar manner with the species that inhabit Central Europe. For Central Europe as a whole he claims 76 species out of a total of 230, which are disposed through the different countries as follows: viz. Austria, 59; Roumania, 24; Servia, 22; North Italy, 17; Switzerland, 15; Germany, 11; Poland, 7; Denmark, 5; and South Sweden, 4. His descriptions are clear and concise, but he has followed the Continental authors in classing as species many types which most English writers would place as varieties. None of the species are new, but it is a great convenience to have them all brought together, and treated on a uniform plan. The book is dedicated to Cardinal Haynald.

Materials for a Flora of the Malayan Peninsula. By Dr. G. King, F.R.S. No. 2. 93 pages. (Calcutta, 1890.)

THIS is a second part of Dr. King's Flora of the Malay peninsula, reprinted from the Journal of the Asiatic Society of Bengal. It covers the orders Bixineæ, Pittosporeæ, Polygaleæ, Portulaceæ, Hypericineæ, Guttiferæ, and Ternströmiaceæ. These were dealt with in Hooker's "Flora of British India" in 1872-74. Since that time a large amount of new material has been accumulated, principally by Kunstler, Scortechini, and other collectors whom Dr. King has sent out. Out of the orders just enumerated the first and two last are well represented in the Malay peninsula. In Bixineæ, Erythrospermum, known before only in Mauritius and Ceylon, is now recorded from Perak, an endemic species. In the same order the two curious Malayan genera, Teraktogenes, of Hasskarl, and Ryparosa of Blume, are added to the Indian flora, and four species of the former, and six of the latter, all endemic, are here for the first time described. In Polygaleæ there are ten new species of Xanthophyllum. In Garcinia, which has lately been fully dealt with in Pierre's "Forest Flora of Cochin China," fifteen new species are described out of a total of thirty-six now known in the Malay peninsula. In Calophyllum there are six new species, in Kayea four, and in Ternströmiaceæ two new species of Adinandra, one of Ternströmia, one Eurya, one Actinidia, two of Pyrenaria, and three of Gordonia. The publication of Hooker's "Flora Indica" has given the Indian botanists a firm platform to work upon, and it is very gratifying to find that so much has been done within so short a time, and that the working out of the new material has fallen into such competent hands.

The Colonist's Medical Hand-book. By E. A. Barton. (London: Cassell and Co., 1890.)

THE author explains that this little volume has been "written expressly for the use of colonists and squatters, who are entirely out of reach of medical assistance." A more suitable book of the kind could not be at their disposal. They will readily understand his directions, and in recommending appliances for the treatment of emergencies he has taken care to refer only to such as are likely to be found in any squatter's hut.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Romanes on Physiological Selection.

AS Dr. Romanes now declares that the essence of his theory of physiological selection is "that some amount of infertility characterizes the distinct varieties which are in process of differentiation into species," and that the occurrence of infertility among the members of an undifferentiated species is secondary and comparatively unimportant, I ask leave to quote one or two more of his original statements, in addition to the four emphatic passages quoted in my communication of November 27.

(1) "When accidental variations of a non-useful kind occur in any of the other systems or parts of organisms, they are, as a rule, immediately extinguished by intercrossing. But whenever they happen to arise in the reproductive system in the way here suggested, they must inevitably tend to be preserved as new natural varieties, or incipient species. *At first the difference would only be in respect of the reproductive system; but eventually, on account of independent variation, other differences would supervene, and the new variety would take rank as a new species*" (NATURE, vol. xxxiv. p. 316).

The words I have italicized show clearly that variation in fertility only was what Dr. Romanes then claimed as essential to his theory. Again, after referring to variations in the season of flowering as a "well-known and frequently observed cause" of isolation, he adds:—

(2) "But it is on what may be called spontaneous variability of the reproductive system itself that I mainly rely for evidence of physiological selection" (*l.c.*, p. 337).

The meaning of this is still further enforced by other passages. After discussing the supposed causes of infertility, he says:—

(3) "Why should we suppose that, unlike all other such variations, it can never be independent, but must always be superinduced as a secondary result of changes taking place elsewhere? It appears to me that the only reason why evolutionists suppose this is because the particular variation in question happens to have as its result the origination of species" (*l.c.*, p. 339).

And again:—

(4) "It appears to me much the more rational view that the primary specific distinction is likewise, as a rule, the primordial distinction; and that *the cases where it has been superinduced by the secondary distinctions are comparatively few in number*" (*l.c.*).

Notwithstanding the passages I have now quoted, emphasizing eight times over, in different ways, that the theory is essentially one of variations as regards fertility and sterility alone, Dr. Romanes now says that, even if all this is wrong, "the principle of physiological selection, as I have stated it, is not thereby affected." If this is not an absolute change of front, words have no meaning; and it is further shown to be so by the fact that Dr. Romanes acknowledged that Mr. Catchpool had "very clearly put forward the theory of physiological selection." But Mr. Catchpool clearly distinguished between the old theory that species arise *first* by variation in form and structure, and only *gradually* become mutually infertile, and the new theory that they arise "by spontaneous variations in the generative elements, and are in this case *originally* mutually infertile, but only *gradually* become otherwise divergent" (*l.c.*, vol. xxxi. p. 4).

That this was the essential and original "physiological selection," that was claimed as supplying the missing link required to make the origin of species by natural selection a reality, is yet further shown by the repeated statements that physiological "selection" is a powerful preservative agent. Besides the statement already quoted, that variations in fertility "cannot escape the preserving agency of physiological selection," we have the assertion, quoted above, that such variations "must inevitably tend to be preserved as new natural varieties or incipient species," and the following still more emphatic assertion:—"Neither are we concerned with the degrees of sterility which the variation in question may in any particular case supply. For whether the degree of sterility with the parent form be originally great or small, the result of it will in the long run be the same: the only difference will be that in the latter case a greater number of generations would be required in order to separate the varietal from the parent form."

Now my contention has always been, and still is, that there is no principle at work which can accumulate or even preserve the variations of infertility occurring in an otherwise undifferentiated species, and that the term physiological "selection" is therefore a misnomer, and altogether misleading. If Dr. Romanes will carefully work out numerically (as I have attempted to do) a few cases showing the preservative and accumulative agency of pure physiological selection within an otherwise undifferentiated species, he will do more for his theory than volumes of general disquisition or any number of assertions that it *does* possess this power.

My next contention is, that this is the only new part of his theory—as he himself shows by his reference to the ordinary view, of sterility following other changes, as that which "evolutionists suppose." All the rest is to be found more or less fully discussed in Darwin's works; and I myself claim only to have carefully studied Darwin's facts, and his brief but most suggestive discussion of them in his chapter on "Hybridism" (vol. ii. of "Animals and Plants under Domestication"), and by arranging them more systematically to have shown that they do really give a fairly consistent and sufficient solution of the problem. The only part of my work I claim as a distinct addition to the theory is the proof that, under certain conditions that appear to me probable, natural selection *is* capable of increasing incipient infertility between distinct races or varieties; and the same view was submitted to Darwin twenty years ago.

Lastly, I totally and emphatically deny that any portion of my facts or conclusions on the subject were derived from Dr. Romanes's writings on "physiological selection." The only two sentences he has quoted from my book to prove that I have done so merely express what he himself has declared to be the common opinion of evolutionists, and which is also the direct outcome of the facts collected by Darwin. If this is "the whole essence of physiological selection," then physiological selection is but a re-statement and amplification of Darwin's own views, since he certainly assumed that "some amount of infertility" characterized "some varieties" of animals and plants, and that this infertility, when it occurs, is of some use in preventing the swamping effects of intercrossing. I feel sure that if *this* had been stated, at the outset, to be what was termed "physiological selection," no discussion would have arisen as to the principle involved, but only as to its novelty and as to the appropriateness of the name given to it.

If now, notwithstanding his repeated and emphatic statements that variation as regards fertility in otherwise undifferentiated species was what constituted the basis of his theory of physiological selection, Dr. Romanes continues to assert that I have adopted that theory "purely and simply, without any modification whatever," it will show that our respective standards of scientific reasoning and literary consistency are so entirely different as to render any further discussion of the subject on my part unnecessary and useless.

ALFRED R. WALLACE.

A Large and Brilliant Fire-ball Meteor.

ON Sunday night, December 14, between 9h. 40m., and 9h. 45m. G.M.T., I had the good fortune to witness the display of a most magnificent fire-ball meteor. It rose rapidly with a bright blue trail from an altitude of 6° above the horizon, at a point 7° south of west, and in about 7 seconds of time attained a culminating altitude of 55° at a point 19° north of west. Two large trees interlaced prevented me from seeing the head of the meteor till shortly before its culmination, but the light given out by it soon after its first appearance was equal to that of the full moon, and at culmination it much surpassed the light of a full moon in a cloudless sky. The ball seemed to be of a most dazzling bluish-grey colour, and it had a diameter of at least three-quarters of a degree. The disk presented a nebulous appearance with radiations within it as from a centre, but was well defined, except on its lower edge. The glare was almost too much for eyesight, and although the night was very frosty, calm, and clear, all the stars in the west became invisible. I turned to look again very shortly after, and at 5 seconds from culmination found the meteor had become a small yellow ball only one-twelfth of a degree in diameter, and was dropping ruddy sparks. It then disappeared at an altitude of 23° towards a point about 51° north of west. My impression was that this meteor was at no great distance from this place in any part of its course (lat. 51° 20′ N., long. 3m. 0s. E.). I noted the positions relatively to trees and tall shrubs, and measured them exactly with a theodolite this morning. To-day I hear that the fire-ball was seen to fall by a man in Chestnut Street, a hamlet on the Maidstone road, and then appeared quite close to him. The direction of fall accords fairly well with my own observation, and would make it descend about two and one-third miles from me. At culmination I should say it seemed very much nearer to me, considering especially its great apparent size at that time. I heard not the slightest noise either of rushing or bursting.

A. FREEMAN.

Murston Rectory, Sittingbourne, Kent, December 15.

ON Sunday, the 14th inst., about 9h. 45m. p.m., I was entering my house by the back door, when the whole place was so brilliantly illuminated that I momentarily supposed there had been a flash of lightning. That erroneous impression was at once removed by the continuance of the light. Wheeling round, I saw a splendid meteor of the fire-ball type, descending obliquely through the sky. Though the Monday newspapers reported serious fog in London on the previous day, yet the night sky at Loughton was perfectly clear; and it was easy to see that the meteor in its descent was passing a little to the right of the constellation Gemini, in a direction nearly, but not quite, parallel to a line joining Castor and Pollux. The head, which was downwards, was a large oval mass of light. The tail was not a mere thread of silvery radiance, like those of November 1866; it seemed broad, irregular on the edges, and sending out sparks. The fire-ball had not descended far when it vanished among a shower of sparks, which also very speedily disappeared. I heard no rushing sound during its course, and no noise of an explosion when it came to its end.

As the time available for observation extended to only a few seconds, it is possible that there may be some error of detail in the foregoing statements. I shall not, therefore, call them observations, but mental impressions of what took place.

ROBERT HUNTER.

Forest Retreat, Staples Road, Loughton, Essex,
December 16.

Attractive Characters in Fungi.

IN the communications which have recently appeared in your journal on this subject, it has been taken for granted that, in the development of *spores* into *mycelium*, the former must necessarily pass through the body of an animal host. We have no scientific evidence of this. I am inclined to think that the theory is a remnant of the old superstition that toadstools are the result of the excrement of toads, and that we must seek for more natural processes of fertilization if we are to solve the mystery. Unbelief is sometimes the nearest road to a right faith. Scepticism is often the gate to truth. It is at least desirable that those who are investigating the subject should approach it unfettered by a theory which is yet destitute of proof, and should direct their researches to ground which is not littered with what may be only the fragments of an exploded superstition. My own observations tend to convince me that germination of the spore and development of the mycelium are alike dependent upon conditions of soil, modified by atmospheric influences, fertilizing agents, &c., &c. It may be added that the solution of the problem is rendered more difficult by the apparently inexplicable fact in Nature, so strikingly exemplified in the field of mycology,

"that of fifty seeds
She often brings but one to bear."

The countless millions of spores which never reproduce their kind must be transmuted into other conditions of being, to form part of the "living whole" of the universe, in which nothing can be lost.

J. S.

Glamis, December 5.

Some Habits of the Spider.

IT would be strange indeed, if, as your correspondents infer, there is no record of the gyrating habit of a species of geometric spider so common as even to be well known to Londoners who have a garden. It may be that Kingsley referred to this species, but his "Water Babies" is not found in scientific libraries. It occurred to me, last September, whilst amusing myself by making some of these spiders gyrate, by blowing on or gently touching them, that the instinct, in this kind, is in a decadent state; it does not appear well suited to a heavy-bodied, sharp-legged species like this one, and is certainly much less perfect than in other species possessing a similar habit.

Some years ago, when describing the habits of some Argentine spiders, I mentioned a species of *Pholcus*, abundant in La Plata, with legs of extraordinary length, in colour and general appearance something like a crane-fly, but double the size of that insect. When approached or disturbed in any way, it gathers its feet in the centre of the web, and swings itself round and round with the rapidity of a whirligig, so that it appears like a very slight mist on the web, and offers no point for an enemy to strike at. Here the correspondence between structure and habits is very perfect; the slimness and great length of the legs causing the creature, at the moment the swift revolutions begin, to seem to disappear from sight; and, owing to the string-like form of the legs, the fatigue experienced is probably very much less than the action would cause in a stout short-legged spider like the English species. At all events, it can revolve for fifteen or twenty seconds at a stretch; and, if the cause of alarm continues, it will perform the action no less than three times before quitting the web. The English spider exhausts itself in a few seconds.

Those of your readers who are interested in the habits of spiders will find the paper referred to in the *Gentleman's Magazine* for 1884. Some of my observations contained therein, I find, have been served up—after a fashion, and (of course) without acknowledgment—in a spider article in the current number of *Longmans' Magazine*.

W. H. HUDSON.

"Nowhere can Mathematics be learned as at Cambridge."

THESE words are ascribed to Dr. Hopkinson in his speech at the Royal Society on behalf of the medallists; and as they are calculated to sustain a belief which, Heaven knows, is already widely enough prevalent among even tolerably well-informed people in England—the belief, namely, that no one but a Cambridge Wrangler is worth thinking of as a teacher of mathematics—perhaps you will allow me to enter a protest.

In the department of applied mathematics, thanks to the work of Thomson, Tait, and Clerk Maxwell, Cambridge is supreme, and so far Dr. Hopkinson is right. The weakness of the Cambridge system has always been on the side of geometry; and I am sure that those who studied this subject under Hamilton, Salmon, and Townsend (to go no farther back), will agree with me in saying so. It is a weakness apparent in almost every work emanating from Cambridge. What would the subject of conic sections, for example, be, if Salmon had not shown how it should be treated? The answer is easily supplied by some of the Cambridge works on the subject which are still in extensive circulation in England. As a result of the belief which Dr. Hopkinson seeks to strengthen, the schools and Colleges throughout the whole country are becoming dominated by Cambridge methods exclusively, all appointments in them being virtually filled with Wranglers and no others; and hence we shall have, in time, a dead-level of sameness of method and thought which will partake of whatever shortcomings may characterize the Mathematical Tripos. Is this result desirable?

GEORGE M. MINCHIN.

R.I.E. College, Cooper's Hill, December 11.

THE DARKNESS OF LONDON AIR.

ONCE more the inhabitants of London are suffering from the inconvenience, that a darkened atmosphere naturally causes. This darkened atmosphere usually commences towards the end of October, and continues off and on sometimes to the end of February—that is, for a period of some sixteen weeks we partially and at times wholly deprive ourselves of the full benefit of the sun's rays, and live in a state of artificial darkness; and when we consider how very little daylight there is during the winter months (even under the best of conditions), it is surely very foolish to reduce the daylight, and create darkness in place of the daylight.

Is anything being done to remedy this state of affairs?

Apparently very little is being done to make matters better, whilst on the other hand a good deal is being done to make things worse; for instance, each year sees thousands of new buildings added to London, many of these buildings being factories and workshops.

We have now (within the Metropolitan area) some 765,000 tenements, and at present (with the exception of a few Acts dealing with factory smoke), the countless chimneys of these numerous buildings are permitted to belch forth volumes of sooty smoke, almost without any check whatever. As for the great majority of the buildings in London (that is, the dwelling-houses), we positively have no means of controlling their smoke.

Under these circumstances it is hardly very surprising, that the atmosphere over London in the winter is so unnaturally dark, and it is further not to be wondered at that we have to expend (or rather waste) vast sums of money in supplying ourselves with artificial light, to enable us to carry on our daily business. It is needless to point out that this outlay would be unnecessary, if we were really to adopt means to deal effectively with this smoke nuisance.

In NATURE, vol. xxxix. pp. 441 *et seq*, various results were given, which were intended to show, in an easily-understood manner, how dark the London air is during the winter-time, owing to smoke fog; it was also shown that other large towns suffer from the same cause.

It is now proposed to give some of the results of a few more observations, taken in London during the winter of 1889-90.

Table I. gives the results obtained in two districts in London, one being at the West End and the other at the East End, about 9 miles apart.

TABLE I.

District in London in which the chart was kept.	December 1889.	January 1890.	February 1890.	Total number of hours during which artificial light was used.
Hammersmith, W.	10	3½	3	16½ hours
Homerton, N.E.	68	38	9½	115½ hours

It will be seen that at Homerton the inhabitants lived for about 115½ hours (during the three months named) in a partial state of darkness during the day-time, and if we consider how short the average length of each day is at this time of year, we find that out of the 90 days concerned, nearly 14 days were practically turned into nights, causing both inconvenience and expense.

During the month of December 1887, and the months of January and February 1888, the number of hours when artificial light was used at Homerton reached the total of 67¼ hours.

TABLE II.—*Chart for Black or Dark Yellow Fog.*

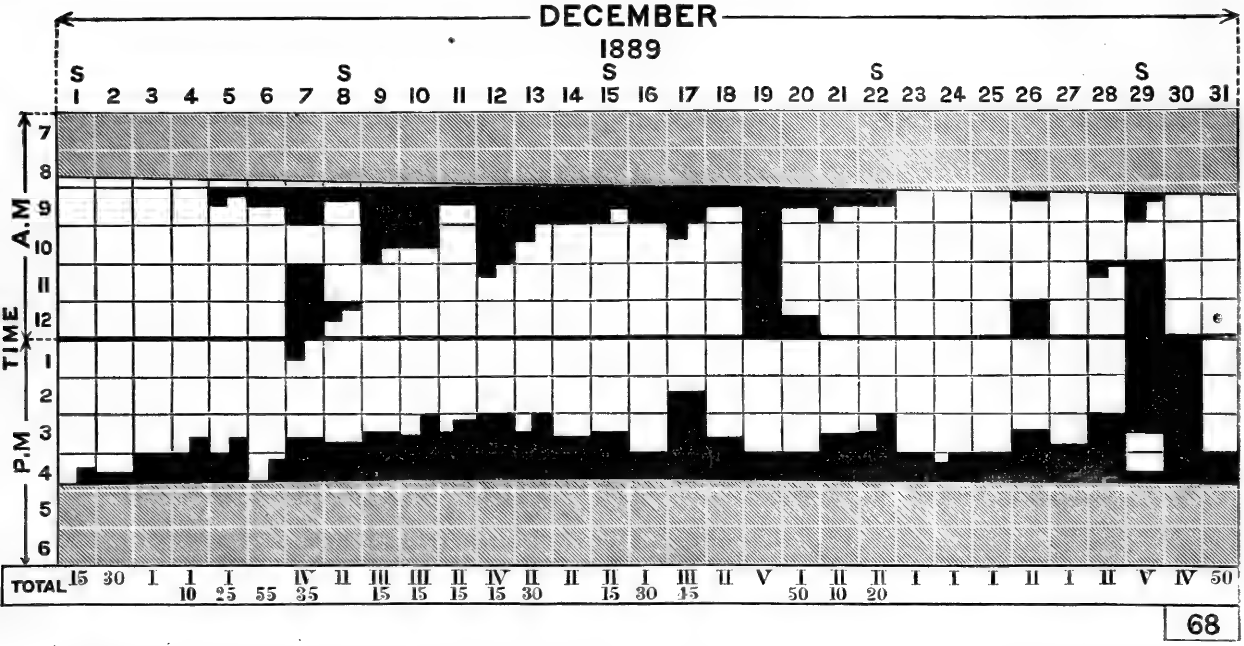

Table II. shows in detail, the kind of chart used to record the darkness caused by smoke fogs. I am indebted to a friend for partly suggesting the form of chart which is given in this table.

The original chart (only a portion being given here) was divided into 2160 squares, every 24 of these squares representing one day, and each single square one hour; these single squares are again subdivided into four parts of 15 minutes each.

The grey colour shows the night-time, the white the day-time, and the black denotes the time each day during which partial darkness prevailed owing to fog.

To show the serious way, in which this artificial darkness of the London air interferes with the numerous kinds of work, that depend upon a clear atmosphere and good light, various records were kept during the winter of 1889–90.

The results of two of these records are given below.

The photographer is, perhaps, one of the greatest sufferers from this artificial state of darkness during the winter-time.

There are various methods in use by which photographs are reproduced, and most of these methods depend on good natural light; Table III. deals with the "silver process."

TABLE III.—*Photography (Silver Process).*

	November 1889.	December 1889	January 1890.	February 1890.	March 1890.
Number of days on which observations were taken in each month	26	24	27	24	26
Number of days when no copy could be printed, owing to the darkness of atmosphere	7	10	7	3	5
Longest time taken to print a single copy in one day [1]	5h. 10m.	5h. 45m.	4h. 40m.	4h. 45m.	3h. 0m.
Shortest time taken to print a single copy in one day...	2h. 5m.	3h. 35m.	2h. 15m.	1h. 25m.	1h. 5m.
Average time taken to print one copy in so many days in each month	Days 19 — Time taken $3\frac{5}{19}$h.	Days 14 — Time taken $5\frac{3}{14}$h.	Days 20 — Time taken $3\frac{4}{5}$h.	Days 21 — Time taken $3\frac{1}{21}$h.	Days 21 — Time taken $1\frac{3}{7}$h.

[1] (*a*) In fine clear weather, it takes about 30 minutes to print a single copy. (*b*) Rain was the cause of no copy being printed on certain days; this remark applies to Table IV. as well.

These observations were taken at Ealing, London, W. It is hardly necessary to point out that Ealing is far away from the centre of London.

The record was kept daily (Sundays and Bank Holidays excepted) during the five months named in Table III.

It will be seen, that the shortest time taken to print a single copy on one of the 127 days in question, was about twice as long as it would have taken if the atmosphere had been clear, &c.; it will also be seen that, out of the 127 days on which observations were taken, on no less than 32 days no copy could be printed at all.

Table IV. deals with a method of copying drawings known as the ferro-prussiate process; this process is very extensively employed by architects, engineers, &c.; it absolutely depends upon a clear atmosphere.

TABLE IV.—*Ferro-Prussiate Process for Copying Drawings.*

	November 1889.	December 1889.	January 1890.	February 1890.	March 1890.
Number of days on which observations were taken	21	15	15	17	22
Number of days when no copy could be printed owing to the darkness of atmosphere	9	9	5	4	6
Longest time taken to print a single copy in one day [1]	7h. 30m.	4h. 15m.	4h. 0m.	1h. 30m.	0h. 35m.
Shortest time taken to print a single copy in one day	0h. 25m.	1h. 20m.	0h. 15m.	0h. 5m.	0h. 4m.
Average time taken to print one copy in so many days in each month	Days 12 — Time taken $2\frac{1}{6}$h.	Days 6 — Time taken 3h.	Days 10 — Time taken $1\frac{4}{5}$h.	Days 13 — Time taken $\frac{8}{13}$h.	Days 16 — Time taken $\frac{1}{4}$h.

[1] In fine clear weather it takes about 4 minutes to print a single copy.

The observations were taken at New Cavendish Street, Portland Place, W.

Out of the 91 days on which a record was taken during the five months named in Table IV., on 33 days it was found impossible to print a single copy of a drawing, and on one day only could a copy be printed in 4 minutes, and this was on March 14, 1890; about 4 minutes is the shortest time possible, that a clear copy can be printed in.

It is, perhaps, unnecessary to give any more results in this paper, to help to prove the existing state of artificial darkness caused by these smoke fogs; but would it be asking too much, if we were to request the London County Council to take steps at once to enforce rigorously the existing Acts of Parliament, which have been framed to deal with factory smoke, and to consider (in a comprehensive and thorough manner) the best means of coping effectively with the smoke nuisance generally?

W. HARGREAVES RAFFLES.

VIBRATION-RECORDERS.

AN interesting paper, by Prof. John Milne, F.R.S., and Mr. John Macdonald, was read before the Institution of Civil Engineers on November 25. The authors presented an account of certain instruments which had been designed to register the oscillations and vibrations of trains, so as to give an automatic record of the run, and information as to the condition of the track. These instruments were modified forms of seismographs, the ordinary earthquake instruments being affected so much by the suddenness of the jolts, and by changes in inclination, as to be unsuitable for this purpose.

The apparatus for recording vertical movements consisted of a clock-spring coiled upon an axle, and connected with a lever carrying a weight in such a way that when the spring was wound the weight was supported by it. The result of this combination was, that for up and down movements of the apparatus some point in the weight remained at rest, and the relative motion of the apparatus and the weight was recorded by means of a pointer attached to the lever.

Horizontal vibrations were registered by the movement of pointers attached to two pendulums, the planes of motion of which were at right angles to each other. The simplest form of pendulum was a metallic cylinder, free to swing on pivots placed on its upper edge. The oscillations of the pendulum might be controlled by giving a certain frictional resistance to the movements of the pointers, as, for instance, by increasing the pressure upon the writing point. Another method of making the vibrations of the pendulum dead-beat, by coupling together two pendulums with a sliding joint, was also shown.

The recording-surface might be a drum, covered with metallic or ordinary paper, and driven by clockwork, the pointers being strips of metal, pencils, or pens; and to obtain a record extending over a considerable period a long band of paper rolled on a drum, as in the Gray-Milne seismograph, was pulled over another drum and wound up on a third, driven by its own system of clockwork.

Reference was made to fifty-eight locomotives now in Japan, on which experiments were carried out. In England, diagrams had been taken in carriages running on the London and North-Western, the Caledonian, the Great Northern, the South-Eastern, and the Metropolitan Railways; and in America a diagram, the original of which was exhibited, was taken, showing the motion of a carriage between New York and San Francisco, a distance of about 3300 miles.

As the diagrams produced by the vibration-recorder were evidently connected with the balancing of the engines, details of the weights of reciprocating parts and the balance-weights were given, together with the equivalent balance-weight, which was determined experimentally in the following manner. A pair of wheels, with their balance-weights, and crank-pins, were placed on the rails; a large round steel ring was then hung from the crank-pin, and from this weights were suspended until a balance was obtained. This weight hung upon the crank-pin was called the equivalent balance-weight, and it was found that when this weight was nearly equal to that of the reciprocating parts—that was to say, when the horizontal component of the energy due to the reciprocating parts was balanced—the diagrams for longitudinal motion were small.

Most of the diagrams were taken on locomotives running on the line between Tokyo and Yokohama, a distance of 17¾ miles, and they showed that there was a relationship between the character of the line and the recorded movements. Soft ground could be distinguished from hard ground, and the effects of bridges and culverts were recorded, all diagrams on the same line showing the same characteristics.

As an illustration of the use of the instrument, two diagrams were shown, taken on different engines running over the line from Shinbashi to Yokohama, the paper moving at the rate of 1 inch to the minute. It was pointed out that, as Shinagawa was approached, the diagram became larger. This was explained by the fact that this portion of the track rested on the mud of Tokyo Bay, and was, therefore, soft and yielding. At the third minute after starting, a sudden movement of the pointer occurred as the engine passed one of the culverts, but the cause of this jerk had not been determined. The train was seen to have left Shinagawa two minutes late, and to have stopped at Omori a minute and a half, instead of one minute, the schedule time. Between Omori and Kawasaki there were irregularities indicating soft places, but the most important mark occurred in the second span of the 40-feet girders forming the waterway leading up to the large bridge at Kawasaki. This mark was found regularly in all the diagrams, and a staff of workmen who knew nothing of the experiments having been sent to examine the place, reported that a sleeper on the second span of the down track yielded, when a train passed, twice as much as any of the other sleepers. Between Tsurumi and Kanagawa the diagram was rather larger, indicating a soft place that required attention. Yokohama was reached four minutes late, the places where time was lost being easily determined upon a close examination of the diagram.

The record of longitudinal motion was found to show most clearly differences in balancing, the size of the diagrams upon engines which differed only in the balancing having been as 6 to 27. A striking feature in the diagram of longitudinal motion was that it indicated ascents and descents by deviating to the right and left of a median line. Curves were marked in a similar manner by the portion of the instrument recording transverse motion.

The observation that certain locomotives gave a larger longitudinal diagram than others suggested that such engines were not exerting their power in an economical manner. It was found that the engines which had used the least coal per mile were those in which the difference between the weight of the reciprocating parts and the equivalent balance was small; and, on the contrary, in those engines where the difference was large the consumption of coal and oil was considerably greater. It occurred to the authors that engines yielding different diagrams might show a difference in the wear of their tires. The data obtainable were meagre, but they appeared to indicate that those engines which gave a small diagram for longitudinal motion did not wear out their tires so quickly as others.

The conclusions arrived at by the authors were:—(1) The vibration-recorder might be of value to those who had to deal with the management of the traffic, inasmuch as it furnished details of the times of stoppage and the speed at any part of the run. (2) The instrument might be used by those who had to inspect lines. Variations due to carelessness on the part of the plate-layers were recorded. Curves, ascents and descents, and even slight variations in grading, were indicated; faults in sleepers, irregular yieldings on bridges, soft portions of the track, and other imperfections, were definitely marked; and changes in the permanent way could be at once detected if such diagrams were taken at intervals. (3) The vibration-recorder might furnish information of value with regard to the manner in which a locomotive should be balanced, the vibrations due to this cause being measured by the diagrams for longitudinal and vertical motion. For this purpose, diagrams might be taken on a surface running at the rate of 1 inch per second. In this case each vibration of the locomotive was recorded separately, and from these diagrams the maximum acceleration of each backward and forward motion had been calculated.

GLACIAL CLIMATE.[1]

EVERY fragment of evidence, which can serve to show us the character of the climatal conditions during the last glacial period, is so important that I venture to present certain facts which, so far as I am aware, have hitherto escaped attention. The evidence I mean to discuss is found in America and Europe in the regions immediately south of the glaciated areas of the two continents. It is a well-known fact that in the present condition of the climates of the earth, the decrease in temperature as we rise above the sea is about 3° F. for each 1000 feet of altitude. Local circumstances may considerably affect this variation, but the range is not great. If glaciers were by the refrigeration of the climate restored to the surface which they occupied during the last ice period, we should expect to find the line of perpetual snow rising as we went southward about 3030 feet for each degree of latitude.

If, on an inspection of the areas glaciated during the recent ice epoch, we should find that this principle in the distribution of the glacier did not hold, we should apparently be justified in the supposition that the glacial climate was not due to greater cold than that which exists at present. Any departure from the normal rate of ascent of the perpetual snow-line in the region south of the glacier would be likely to throw some light on the climatal conditions prevailing during the time when the continental ice-sheets were developed.

Beginning our inquiry with the Appalachian section of Eastern America, we find there a region in many ways well suited for the determination we seek to make. The principal front of the ice stretched across the continent on a line which is now well determined. It is unmistakably evident that it crossed the valley of the Ohio at Cincinnati, and extended a little distance south of that stream into Kentucky. I have recently re-examined the evidence which goes to show the presence of the ice at the above-named point, and have no doubt as to the goodness of the determination. At this point the surface of the country lies at a height at no point exceeding 900 feet above the level of the sea. From this position the level of the country gradually rises in a southerly direction until in the synclinal mountains near Cumberland Gap it attains a height probably exceeding 3500 feet. From this elevation the profile descends in the broad valley of the Upper Tennessee to about 1000 feet above the sea-level; thence it again rises until, in the mountains of North Carolina, we enter a field where many peaks rise to more than 6000 feet in height. From the front of the ice-sheet near Cincinnati to the central part of the North Carolina mountain district is about 200 miles. It is to be observed that the whole of this district is within the same great valley, and in a region where the isotherms at the present time follow each other with normal curves. We may therefore fairly conclude that, under the usual conditions of climate such as prevailed in North America, the ice-line should be found in the mountains of North Carolina at the height of 2000 feet above the base of the glacier at Cincinnati, or, say, at 3000 feet above the level of the sea. From that level to the top of the North Carolina mountains, or, say, for the height of 3500 feet, we should have indications of glacial conditions. A tolerably careful investigation of this country has shown me no evidence of ice action whatsoever, and all the other students of the subject who have visited this area have failed to find any facts which might afford even a supposition of glacial work in that field. I am therefore compelled to assume that the slope of the snow-line rose so rapidly from the ice-front at Cincinnati southward that it passed above the summits of these mountains.

If the elevation of western North Carolina was in the form of an isolated peak, we might have less confidence in this indication. But the district of land which should have lain much above the snow-level is some thousand square miles in area, a field sufficiently great to have developed very extensive glacial areas in case the peaks lay above the line of perpetual snow. The same considerations, though in a less accented way, are met when we examine the highlands of the Blue Ridge in Virginia, or the Alleghany Mountain district on the uplands of Virginia and West Virginia. A large part of the Blue Ridge in Virgina is high enough to have been the seat of glaciers, provided the snow-line were anywhere near the level of the glacial sheet where it crossed the existing Atlantic coast. The traces of glacial work in the Blue Ridge are extremely scanty. At the western extremity of Rock Fish Gap, immediately south of the Chesapeke and Ohio Railway, near its junction with the Shenandoah Valley Railway, there are accumulations which apparently are to be classed as glacial. This point is about 1600 feet above the level of the sea. If this accumulation be really of glacial origin, it apparently establishes the height of the ice-front in the Shenandoah, but as yet I must regard the indication as somewhat questionable. In the Alleghany Mountains west of Covington, Va., there are deposits which I am disposed to consider of a glacial nature. At this point the deposits lie about 2000 feet above the sea-level. These are the southernmost points at which I have found any satisfactory indications of glacial work, in the region south of the Potomac, and, until further investigated, both of these deposits must be regarded as of doubtful character.

In Europe, in the region south of the Alps, we find the facts similar in their character to those existing in North America. During the last glacial period the ice-sheet extended down on to the Italian plains, unquestionably attaining levels less than 1000 feet of altitude above the level of the sea, and probably occupying positions not more than 500 feet above that level. From my observations on the field I am disposed to think that the general mantle of the ice covered the southern face of the Alps down to within a few hundred feet above the sea. From 150 to 200 miles south of the Alps in the mountains of Tuscany, we have an extensive surface rising 4000 or 5000 feet above the sea. A careful search over much of this field showed me no evidence of occupation by ice. At the present rate of rise in the perpetual snow-line in Switzerland we should expect an ascent of that plane about 1500 feet in passing from the foot of the Alps to the Apennine Mountains north of Florence. We have thus a case similar to that we find in the North Carolina mountains, in which there are elevations just south of the continental glaciers of a sufficient height to have been covered by ice under normal circumstances, but where the evidence of such coating is conspicuously wanting.

I have endeavoured to apply the same considerations to the glacial phenomena of the Rocky Mountains, but the facts are as yet so imperfectly in hand that I have not been able to determine the relative altitude of the sheet in a satisfactory manner. This, however, may be said: the distinct glacial accumulations in Colorado probably do not extend below the level of 6000 feet. As this region is about on the parallel of the mountains of western North Carolina, it may perhaps indicate that the snow-line lay throughout the southern parts of the United States above the summits of the Carolina mountains. It seems to me, however, that in the existing state of our knowledge of the distribution of the glacial sheet in the Cordilleran section we cannot attach much importance to this evidence.

We have now to consider the possible explanation of the facts above adduced. Assuming that the relative height of the surface occupied by the glacier, when it crossed the Ohio River, and that of the region within two hundred miles south of it, even during the ice epoch,

[1] By Prof. N. S. Shaler. Reprinted from the Proceedings of the Boston Society of Natural History, vol. xxiv. parts 3 and 4, May 1889–April 1890.

were what they are at the present day, it at first sight seems necessary to suppose that there was a rapid change in the temperature in passing from the ice-front towards the Gulf of Mexico. Before we adopt this consideration, however, we must bear in mind the fact that the ice-sheet of the last glacial period probably advanced for a considerable distance south of the perpetual snow-line, in substantially the same way in which an Alpine glacier descends in many cases to a depth of 1000 feet or more below the fields of enduring snow by which it is fed. Accepting the elevation of the continents as they now exist, and allowing 3° of temperature for each 1000 feet of altitude, it seems likely that the snow-line just touched the summit of the Carolina mountains and came to the surface of the sea near the southern end of Hudson's Bay. In other words, the protrusion of the ice to the south of this glacial snow-line carried it at a distance of near 1000 miles south of the gathering ground. This supposition, however, is of little value, for the reason that the level of the continent was clearly much disturbed during the glacial period, the surface declining to the northward within the glacial envelope, and probably rising to the southward of the ice-front.

It seems to me most likely that during the occupation of the northern part of the continent by glaciers, the southern portion of the continent was considerably elevated. All the streams which discharge into the ocean south of the former ice-front between New York and the Rio Grande show in their lower parts only moderate accumulations of alluvium which has been deposited since the close of the glacial period. They generally enter bays which appear to be the lower parts of gorges which were formed during the period when the area was more elevated than it is at the present time. These facts make it probable that if the mountains of North Carolina varied in elevation from the present height, they were more elevated than at this day. All the facts are against the supposition that we can explain the absence of glaciers in their highlands by supposing that the summits were lower during the ice period than they now are.

It seems to me we are compelled to suppose that the climate in the mountains of North Carolina, and probably in the great portion of the Apennine section south of the Alps, had during the glacial period a temperature not much if any lower than they have at the present time. As far as it goes, the evidence is thus opposed to the supposition that the glacial period was brought about by a general refrigeration in climate of the continents occupied by the sheet.

Within the basin of the Ohio, especially in the valleys of the Upper Tennessee system of waters, we find certain phenomena which lead us to the conclusion that the rainfall in a recent period, probably contemporaneous with the glacial epoch, was more considerable than at the present day. In many valleys which I have observed in that section the *débris* built into the imperfect alluvial plains is of a much coarser nature than that now brought down by the rivers The channels bear the aspect of having recently been the seat of more voluminous streams than now occupy them. This evidence, gained from many points in the Southern Appalachians, leads me, independently of the hypothesis I am now suggesting, to the conclusion that during the last glacial epoch the rainfall of this country was much greater than it is at present. At Big Bone Lick in Kentucky, which lies within a few miles of the southern boundary of the ice-sheet, excavations made by me in 1868 show embedded in the deposits formed by the springs an abundant set of herbivorous mammals, including the mastodon and elephant, an extinct species of buffalo, and a musk-ox kindred to our Arctic species but of much larger size, a species of carabou, indistinguishable from our living American forms. The conditions of this deposit led me to suppose that these animals were probably not more ancient than the glacial period, and that they most likely occupied the surface during the time of abundant rainfall when the marshes were more extensive than at present, a period which if not exactly coincident with the extreme advance of the ice must fall within the glacial epoch.

The abundance of these large Herbivora, the relatively great size of the species, point also to the coincident occurrence of a rather abundant vegetation. If the period indicated by the massive gravels of the torrential streams and the Herbivora of Big Bone Lick be identical, and if this period coincides with the glacial period, as it appears to do, then we may fairly assume that the climatal conditions immediately to the south of the glacial sheet were not those of extreme cold. This evidence has nothing like the sure foundation obtained by the lack of glaciers in the mountains of North Carolina, but as far as it goes it confirms the results of those observations.

It is not my purpose, however, in the present writing to consider the perplexing question as to the cause of glacial climate. I desire only to call attention to the extent to which our glacial streams appear to have advanced, by what we may term forced marches, far to the south of the line of perpetual snow. Although the value of the evidence above noted cannot be determined until the matter has been more carefully brought together and abundantly discussed, the facts seem to me to militate against any hypothesis which seeks to account for the glacial period on the supposition that the climate in the glaciated regions was cooler than at present.

THE SUBJECT-MATTER OF EXACT THOUGHT.[1]

WHEN mathematicians, logicians, and other exact thinkers think and reason, they think and reason about something. What is that something? And wherein consists the infinite variety which it presents? Is it a mere assemblage of detached subjects of entirely different natures? Or is it an harmonious whole, admitting of a definition and treatment which, though perfectly general, will yet preserve the essential characteristics of its component parts?

To judge by the usual habit of thought on these questions, we ought apparently to conclude that the former is the correct hypothesis; but that such a conclusion would be wholly erroneous, there can, I think, be no doubt whatever. The prevailing view is due, I believe, to the want of a proper appreciation of the difference between that which is the essential or necessary matter of exact thought, and that which, so far as the processes of reasoning are concerned, is merely the dress in which that necessary matter is clothed. This dress has, of course, a real importance of its own, and the study of it is not to be undervalued. But when we are investigating the subject-matter of exact thought it is not with it that we are concerned: it is not with the case, but with the works of the clock that we have to do; and thus our anxiety should be to get rid of the environments, to treat them as the "disturbing agents" of the experiments of the physicist, as likely to mislead, and therefore to be eliminated with the most scrupulous care.

That such dress exists in the case of every subject that we investigate is obvious enough; much of it is recognized

[1] The object of this paper is to set forth in as simple and non-technical a manner as possible, the principles which were first formulated in my "Memoir on the Theory of Mathematical Form," published in the Philosophical Transactions of the Royal Society for 1886, vol. clxxvii. p. 1, and a "Note" thereon contained in the Proceedings of the Royal Society, vol. xlii. p 193. which corrects the Memoir in some important particulars. The special applications of the theory principally dwelt on here are considered in detail in a recent paper by me, "On the Relation between the Geometrical Theory of Points and the Logical Theory of Classes," contained in the Proceedings of the London Mathematical Society, vol. xxi. p. 147. The mode of treatment of the whole subject adopted in the present communication must however be regarded as entirely new.—A. B. K.

without an effort. Thus the geometrician must draw the lines of his diagrams of some colour, but never dreams of supposing that the particular colour affects the real matter he is investigating; and the logician, bidding us fix our attention on the relations of implication, contradiction, &c., of the passages he selects for analysis, properly rejects the poetic beauties or philosophic truths they may enshrine as matters with which he is not for the moment concerned. But though there is a great deal of this accidental environment which is readily seen to be such, and is therefore rejected without difficulty, there remains much which, unless attention is expressly directed to its discovery and rejection, is likely to be regarded as the kernel itself, and not as mere husk. In innumerable instances this separation of the essential from the non-essential has, I am satisfied, not yet been effected. That this is so is, to a very considerable extent, due to the practice, no doubt for some purposes a necessary one, of dividing the study of the subject-matter of exact thought into different sciences, such as logic and mathematics, each with its own literature and students, the latter generally misinformed as to the real nature of those subjects which are not their special study. By this divorce of studies the student of either has the dress in which his particular subject is clothed so invariably associated with its essential elements that he fails to regard it as a dress at all, and looks upon it as a part of the naked body itself. No wonder then that such attempts as have been made to define the nature of the subject-matter of certain sciences are in general vague and metaphysical, rather than exact and mathematical; or that there are those who are content to say that logic is the science of "quality," mathematics of "quantity," and therefore their domains are, and should be kept, distinct. Such persons would no doubt be surprised to learn that mathematics is no more the science of quantity only than physiology is the science of the arm or leg; and that the algebra which expresses the relations of quantity is but a drop in the ocean of algebras which the mathematician can point to; another drop, be it observed, being the algebra which expresses the logical relations of classes or propositions to each other.

The essential elements of the subject-matter of exact thought are in reality of an extremely simple character; and, though they exhibit infinite variety, that variety is due to simple and easily defined causes. There is nothing vague or metaphysical about them; but, even when mere figments of the brain, they are precise and definite, with parts and properties which can be analyzed and catalogued, just as much as if they were the elements of a chemical compound, the wheels of a watch, or the organs of a vital structure. Let me try to show that this is so.

I will begin by considering and comparing the essential matter of two "branches of science," which will, I think, be regarded by most persons as of quite different characters, and as very properly relegated to separate and distinct treatises. I refer to the geometrical theory of points, and the logical theory of statements. The investigation will, I hope, fully prepare the way for an acceptance of the general definition of the subject-matter of exact thought which will follow.

I take points first. The geometrician deals, of course, with many things besides points, viz. lines, planes, curves, surfaces, &c.; but points may be considered alone, and it conduces to much greater clearness of ideas to confine ourselves to one species of entity, instead of introducing several into our field of view. I deal therefore with points only. And first let us consider individual points. Euclid says that they have neither parts nor magnitude; but these facts, however true and interesting, are, so far as the exact thought of the geometrician is concerned, beside the mark, and introduce considerations which tend to divert our attention from that which is really essential. When these immaterial considerations are swept on one side, all that we can say about points as individual entities is that they are all exactly like each other, are undistinguished from each other; no remark can be made of one which is not equally true of every other. But there are innumerable other entities about which the same thing can be said; and yet these do not possess those properties which characterize points. To say that points have *positions* is no explanation: it merely leads us to consider positions, and these are really the same things as points. Thus far, then, we have not obtained much insight into the essential characteristics of a system of points.

Let us go a step further and consider *pairs* of points. But even this will help us but little, for pairs of points are geometrically speaking, undistinguished from each other, just as single points are. No remark can be made about any one pair of points which is not equally applicable to every other pair. It is true, no doubt, that in some pairs the points are further apart than in others; but in considering distances we are not considering properties of individual pairs of points, but the relations of certain pairs to each other; and when we consider the relation of one pair of points, a, b, to another pair, c, d, we do not deal with peculiarities of the individual pairs a, b, and c, d, but with a peculiarity of the tetrad of points, a, b, c, d. To put the matter in another way, the geometrical properties of a diagram do not depend upon its size; whether it be enlarged or diminished they remain the same.

We are still, then, as much in the dark as ever as to what there is about a system of points, which gives to it the properties which are discussed by the geometrician; and we must advance yet another step, and consider *triads* of points. And here at last light breaks in upon us. Unlike single points and pairs of points, triads of points are not exactly like each other, and remarks may be made of certain triads of points, which, though true of some others, are not true of all. In the first place, there is the great division of triads of points into *collinear* triads, *i.e.* triads consisting of three points through which a straight line could be drawn, and *non-collinear* triads through which no such line could pass. This division is of fundamental importance, and the consideration of it introduces us to the whole of those geometrical properties which, for reasons into which I need not now enter, are termed "projective." But besides this division into collinear and non-collinear triads, there are apparently subdivisions of the triads of each sort, arising from the differences which may exist in the relative distances of the three points in a triad from each other—in the *shape* of the triangle which they form. The geometrical properties which depend on such subdivisions are known as "metrical" properties. We need not, however, separately consider these subdivisions; for, thanks to the researches of Poncelet and Cayley, we now know that the consideration of "projective" properties comprehends the study of those which are "metrical"; and thus a complete discussion of the results which flow from the division of triads of points into collinear and non collinear triads, would include a full examination of those which arise from metrical subdivisions. In fact, when we consider the metrical properties of triads of points we are not considering triads at all, but collections of a larger number of points, arrived at by adding to the triads certain other points technically known as "the absolute." If we consider the triads alone and apart from "the absolute," *i.e.* if we consider their projective properties, we have only two sorts of triads to deal with, viz. collinear and non-collinear. All the triads of each sort are precisely alike in properties, nothing can be said of one of the triads of one sort which is not true of each of the others of that sort; but every collinear triad differs radically from every non-collinear triad.

All, therefore, that we need now concern ourselves with is the division of triads of points into collinear and non-collinear triads. Now, though the distinction between collinear and non-collinear triads is of fundamental importance, it is not the collinearity and non-collinearity in themselves which are the subjects of consideration by the geometrician. The fact that in a collinear triad the three points are characterized by a symmetry or straightness which is not found in triads of the other species is, so far as the geometrician is concerned, a matter of indifference; it is a piece of accidental clothing which is not an essential part of the subject-matter with which he is dealing. He is concerned with the fact that triads of the one species differ radically from those of the other; but not with the fact that they differ in respect of straightness. With what, then, is he concerned beyond the mere fact that they differ? The answer is, that it is with the way in which the triads of the two species are distributed through the whole system of points; and with the fact that this distribution is not a random one, but is regulated by definite laws, so that if we are told that certain triads are collinear or non-collinear it necessarily follows that certain others are also collinear and non-collinear respectively.

The laws regulating this distribution may be stated as follows:—

Law I.—If the two triads *a*, *b*, *p*, and *c*, *d*, *p* are collinear triads, there exists a point *q* such that the two triads *a*, *c*, *q* and *b*, *d*, *q* are collinear triads.

Law II.—If the two triads *a*, *b*, *c* and *b*, *c*, *d* are collinear triads, so also are the triads *a*, *c*, *d* and *a*, *b*, *d*.

Law III.—No point is absent from the system whose presence is consistent with the foregoing laws.

The distribution of the triads of the two species through the system in accordance with these laws completely determines it as one possessing all those properties which are usually studied by the geometrician. I insert the limitation "usually," because there are certain matters sometimes considered which require other circumstances than those previously referred to to be taken into account. To these I shall return later.

It necessarily, of course, follows from this definite distribution of the distinguished and undistinguished triads that there exists a similar regularity of distribution of distinguished and undistinguished collections of any number of points. But, in addition to this, there also exists a like regular distribution of what may be termed "aspects" of those collections, about which I must say something.

By an "aspect" of anything in the ordinary sense of the word, we mean the appearance which it presents under conditions. If the conditions are altered, we have different aspects of the thing. Thus, a thing presents different aspects when viewed from different standpoints, or when placed among different surrounding circumstances. The conditions may be purely mental. Thus, when we consider the relation of one of a collection of objects to the other objects of the collection, we mentally attach a different degree of prominence to the former object from that which we assign to the latter objects, and we have a particular aspect of the whole collection in view. An aspect of a collection of entities will also be obtained if we regard the entities of the collection as taken in a particular order. It is with aspects of this latter description that we are here concerned. It must not, however, be supposed that the *order*, in the sense of *succession*, is of any importance so far as we are here concerned. All that is material is the fact that the entities are conceived of as taken first, second, third, &c., and that to be taken first is different from being taken second, and so on, the nature of the difference being immaterial; so that an aspect of the sort considered would equally well be obtained by conceiving that each entity of the collection is marked with a different mark of any sort. It is, however, convenient for my purpose to consider the aspects obtained by supposing the entities of the collection to be taken in a particular order; among other reasons, because such aspects admit of being represented in an extremely simple manner; viz. if *a*, *b*, *c*, *d*... represent the entities of any collection of entities, we may represent the various aspects of that collection by arranging those letters in rows, thus *abcd*..., or *bdca*.... Aspects may be different, and yet be undistinguished from each other. Thus, by looking at a sphere from different points of view we obtain different aspects of it, but one of these may be exactly like another. So in the case of an aspect of a collection of any number of points; for example, to take the simplest case, of a pair of points, *a*, *b*. Here the two aspects *ab* and *ba* are different aspects of the pair, but they are undistinguishable from each other; nothing can be said of a pair of points taken in one order which is not true of the pair taken in the reverse order. In other words, a pair of points is *symmetrical*. On the other hand, if a collection of points is unsymmetrical, *e.g.* if it consists of a collinear triad, *a*, *b*, *c*, and one point, *d*, which is not collinear with *a*, *b*, *c*, then we can always find two aspects of the collection which are distinguished from each other, *e.g.* in the given case the aspects *abcd* and *abdc* are distinguished from each other.

The consideration of these aspects of collections of points is of much use in the discussion of the properties of a system of points. To take one simple example. Suppose we were told that the collection of four points, *p*, *q*, *r*, *s*, is undistinguished from the collection *a*, *b*, *c*, *d*, which we have just been considering. Then, though we know that three of the points *p*, *q*, *r*, *s* compose a collinear triad, we do not know which three; but if we are told that the aspects *abcd* and *prsq* are undistinguished from each other, then we know that, since *a*, *b*, *c* is a collinear triad, *p*, *r*, *s* is one also.

Every collection of points has, then, a number of aspects, arrived at by taking the points composing it in every possible order; and of these aspects of the various collections which compose a system of points, some are distinguished from each other, and some undistinguished; and these distinguished and undistinguished aspects are regularly distributed through the system, just as the distinguished and undistinguished collections are distributed. This regular distribution of the aspects is determined by the distribution of the collinear and non-collinear triads of points in accordance with the laws which I have given, and on that distribution alone.

Owing to this regular distribution of the distinguished and undistinguished collections, and aspects of collections, which compose a system of points, that system possesses a specific character or "form," as it may be termed. It is to the possession of this "form" that the system owes its various properties as studied by the geometrician, and it is this "form," and that only, which is the real subject-matter of his exact thought in the study of a system of points.

I do not propose to show here how the various properties of a system of points necessarily follow from the laws which I have given as defining its "form," or how it is that such a system contains sets of points having the characteristic properties of such as lie on straight lines, curves, surfaces, &c. These are all matters of detail involving no new questions of principle, and can be worked out without difficulty by anyone who has a knowledge of modern projective geometry. It is sufficient for my purpose to have indicated the position which "form" occupies in the geometrical theory of points.

Before, however, I pass away from the consideration of points, I must call attention to one or two matters with regard to them, which, as I have already indicated, may on occasion have to be considered by geometricians, and are not covered by the foregoing treatment.

I have hitherto assumed that the coincidence of points implies their identity, and in most geometrical investigations this is taken to be so. We may, however, regard coincidence as amounting merely to equivalence, *i.e.* we may regard coincident points as such that each bears precisely the same relation to all other points.[1] Where a system of points thus includes equivalent points, pairs of points are of two sorts, viz. we have equivalent pairs and non-equivalent pairs. Equivalent pairs are distributed through the whole system of points in accordance with the following law :—

If each of the pairs *a*, *b* and *a*, *c* is an equivalent pair, then the pair *b*, *c* is an equivalent pair.

Another matter to which reference should be made is this. The laws which I have given as defining the "form" of a system of points define that form by specifying the mode of distribution of the collinear and non-collinear triads, *i.e.* of the various *collections* of three points to be found in the system. Nothing is said about the *aspects* of those triads, and thus we do not know, in the case of any collinear triad, which is the mean point of the triad, and which are the extremes—which point lies between the other two. In general it is not necessary that we should know this; in a vast number of geometrical investigations it is wholly immaterial. In certain cases, however, the matter is of importance; and, as its consideration brings out a very interesting and important fact as to the relation between points and statements, I must not pass it over. Here the laws which define the distribution of the collinear triads must not only specify what triads are collinear, but also which is the mean point and which the extremes in each. It must, however, be noticed that the fact that in a collinear triad one point "lies between" the other two is not a material circumstance; all that is of importance is that the one point bears a different relation to the triad from that which is borne by the other two points. It is convenient to denote a collinear triad in which *b* is the mean point, and *a* and *c* the extremes, by the symbol *ac.b*. The laws of distribution of the collinear triads may then be stated thus :—

LAW I.—If we have the collinear triads *ap.b* and *cp.d*, a point *q* exists such that we have the collinear triads *ad.q* and *bc.q*.

LAW II.—If we have the collinear triads *ab.p* and *cp.d*, a point *q* exists such that we have the collinear triads *aq.d* and *bc.q*.

LAW III.—If we have the collinear triad *ab.c*, and *a* and *b* are equivalent points, all the three points, *a*, *b*, *c*, are equivalent.

LAW IV.—If *a* and *b* are equivalent, we have the collinear triads *ac.b* and *bc.a*, whatever point *c* may be.

LAW V.—If the triads *a*, *b*, *c* and *b*, *c*, *d* are both collinear triads, so also are both the triads *a*, *c*, *d* and *a*, *b*, *d*.

LAW VI.—No point is absent from the system whose presence is consistent with the foregoing laws.

I shall have occasion again to refer to these laws, but, for the present, I pass away from the consideration of the geometrical theory of points, and proceed to discuss the logical theory of statements.

In place of points, we have now to deal with statements. Most persons would, I think, say that our new subject-matter is something altogether different from that with which we have hitherto been dealing, and would demur to my observation that, as subjects of exact thought, statements are just the mere entities that points are. "Statements," they would say, "are complex structures; some very complex, consisting, in fact, of a number of other simpler statements combined together by the use of the conjunctions 'and' and 'or'; and, of the simpler statements, even the most simple comprise parts—'terms,' &c.—which cannot be overlooked. It would be absurd to say that all these are to be ignored, and a statement regarded as if it were a mere entity such as a point is."

In answer to such objections, I would point out, on the one hand, that a statement is not other than a mere entity because it happens to be expressed as a combination of other statements, any more than a number is other than a mere number when it is expressed as the sum or product of other numbers. Nor, on the other hand, do we, by regarding a so-called "complex" statement as a mere entity, ignore the other statements in terms of which it is expressed, any more than we ignore certain numbers when we regard the number which is their sum or product as a single number, and not as a sum or product of two or more numbers. Those other statements will not be ignored, but will be regarded and treated each as a distinct entity. Every statement when considered alone is regarded as a single entity. When it is taken in conjunction with others, we see that it bears to them certain relations which we call "inconsistency," "implication," &c.; and, by virtue of the existence of these relations, it may be expressed in terms of those other statements, just as one number may be expressed as the sum or product of other numbers to which it is related.

As regards the "terms," &c., which compose statements, I remark that we shall here be concerned only with the relations of statements to each other, and not with the relations that they bear to "terms" or other things. The relations which statements bear to each other may, of course, be considered and expressed by dealing with the terms, &c., which compose them; and equally the relations of points to each other might be expressed by reference to the straight lines, curves, surfaces, &c., which pass through them: but, just as points have relations to each other which may be considered without reference to other geometrical conceptions, so statements and their mutual relations may, and will here be, discussed without any regard to terms.

But a further objection may be raised to the notion that statements as the subjects of exact thought are mere entities, such as points are, which must be considered and dealt with; and that is, that it leaves no place for those conceptions of the truth and falsity of statements which seem to be of the essence of the logical theory: ideas of truth and falsehood can hardly be associated with mere entities. In order to dispose of this objection, let us consider what the logical theory of statements is, as it is usually understood. Statements, with certain special exceptions to be presently referred to, are conceived of by the logician as admitting of being regarded at will as either true or false. This liberty, which we have to regard individual statements as either true or false, does not extend to all pairs, triads, &c., of those statements; for, in general, if certain statements are regarded as true, there are others which must be regarded as true also, and others which must be regarded as false. Similarly, if certain statements are regarded as false, there are others the truth or falsity of which is thereby determined. Our liberty, then, in this respect is subject to certain restrictions. It is to these restrictions that statements owe those mutual relations which it is the object of the logician to investigate and define.

I have said that there are certain special exceptions to the rule that individual statements are conceived of as admitting of being regarded at will as either true or false. The restriction, in fact, which exists in the case of pairs, &c., of statements, extends equally to the case of individual statements, for there are some which cannot be regarded at will as either true or false, but must be regarded some as always true, and others as always false. These statements are called *truisms* and *falsisms* respectively. Logically speaking, all truisms are equivalent: each bears precisely the same logical relation to every other state-

[1] Observe here the difference between undistinguishableness and equivalence. In order that two entities may be undistinguished, it is sufficient that the relation which one bears to any collection of entities may be borne by the other to a collection which is undistinguished from the former collection. But, in order that two entities may be equivalent, it is necessary that the relation which one bears to any collection of entities should be borne by the other to the *same* collection, and not merely to one which is undistinguished from it.

ment or body of statements; and this is equally the case with falsisms. The introduction of truisms and falsisms into our field of view brings us to the root of the difficulty about the truth and falsehood of statements, and enables us to dispose of it. For to regard a statement as true is merely to ignore the difference between it and a truism—to regard it as equivalent to a truism; and the conception of the truth of a statement is thus simply one as to the *equivalence* of two statements one of which is a truism. In the same way the conception of the falsity of a statement is one as to the equivalence of two statements one of which is a falsism; and generally the logical relation between statements which is expressed by saying that if certain statements are true or false certain others are also some true and some false, is one which may equally well be expressed by saying that if certain statements, one of which is a truism, or a falsism, are equivalent, so also are certain others, one of which is a truism, or a falsism. The truth of a truism and the falsity of a falsism are not matters with which we are here concerned at all, any more than we are with the elegance or conciseness of the language in which they are couched; the question is one merely as to the equivalence of statements, and the relations expressed are such as may and do exist between statements no one of which is a truism or falsism. In fact, truisms and falsisms, as regards the logical relations which they bear to other statements, differ in no material respects from any other statements; and indeed all statements are, so far as their logical relations are concerned, undistinguished from each other; for, whatever relation a statement bears to any body of statements, that relation is also borne by every other statement to some other body of statements.

How comes it, then, it may be asked, that truisms and falsisms unquestionably do appear to bear exceptional relations to other statements? The reply is simple. We are accustomed to consider statements with reference to the relations which they bear to truth and falsehood, *i.e.* to truisms and falsisms, and the verbal shape which they assume in general involves such a reference. In fact, as we shall presently see, whenever the words "*and*" or "*or*" are used, there is such a reference involved. Statements which thus involve a reference, whether express or implied, to the relations which they bear to truisms or falsisms naturally seem to bear exceptional relations to the latter; though in fact, logically speaking, they bear no such exceptional relations.

Statements, then, as subjects of the exact thought of the logician, compose a system of entities which are undistinguished from each other. Let us proceed, as in the case of points, to consider pairs of these entities. At first sight it may seem that pairs of statements are of many different sorts; for two statements may be equivalent, inconsistent, contradictory, one of them may imply the other, and so on. But, as regards certain of these relations, a little examination in the light of the preceding observations will make it clear that they are not really relations between *two* statements at all, but between *three*, one of which is a truism or a falsism. Thus two "inconsistent" statements are such that they and a truism cannot all three be regarded as simultaneously equivalent; and similarly in other cases, which will be considered when we come to deal with triads of statements. There are, in fact, but three species of pairs, viz. *equivalent* pairs, *contradictory* pairs, and *simple* pairs.

An *equivalent* pair consists of two statements which are such that, whatever logical relation one of them bears to any body of statements, that same relation is borne by the other to the same body. Equivalent pairs are distributed among the whole body of statements in accordance with the following law:—

If each of the pairs a, b and a, c is an equivalent pair, then the pair b, c is also an equivalent pair.

A *contradictory* pair, as usually defined, consists of two statements which cannot both be regarded as true or both as false, and the relation considered would therefore seem to be one between *four* statements, and not *two*. This is not, however, really the case. The relation may no doubt be thus defined by reference to the two additional statements—a truism and a falsism; but it may also be fully defined without reference to any such additional statements: viz. two statements are contradictory if they cannot be regarded as equivalent without ignoring all logical relations. Since two contradictory statements cannot be equivalent to each other, it of course necessarily follows that they cannot both be equivalent to a third statement, whether it be a truism or a falsism, or any other statement. Two statements which are a contradictory pair may be said to be *obverses* of each other. A truism and a falsism are obverses of each other.

The following law holds with regard to contradictory and equivalent pairs, viz.:—If a, b and a, c are both contradictory pairs, the pair b, c is an equivalent pair. As however this law is a necessary consequence of certain laws which we shall have presently to consider, I do not include it among the fundamental laws which define the properties of a system of statements.

The third sort of pair, viz. a *simple* pair, is one which is neither an equivalent pair nor a contradictory pair: *i.e.* it consists of two statements which are neither necessarily equivalent nor necessarily non-equivalent, but may at will be regarded either as equivalent or not.

The division of pairs of statements into the three species, and the distribution of the pairs of the different species in accordance with the foregoing laws is not enough to determine the properties of a system of statements; and we must, as in the case of points, go on to consider triads of statements. These are of two sorts, which, for reasons that will presently appear, I term "linear" and "non-linear" respectively. There are other subdivisions of the triads into different sorts, but the division into linear and non-linear triads determines the other subdivisions. As in the case of a collinear triad of points, a linear triad of statements consists of two statements which may be called the "extremes," and one which may be called the "mean." It is such that if the two extreme statements are regarded as equivalent the mean must also be regarded as equivalent to them, and in this respect also it resembles a collinear triad of points. Any three statements which are thus related compose a linear triad, and any three which are not so related compose a non-linear triad. I shall employ the same symbol to denote a linear triad of statements that I employed in the case of a collinear triad of points; viz. a linear triad in which a, b are the extremes and c is the mean statement will be denoted by $ab.c$.

These linear triads are not scattered at random through the whole body of statements, but are distributed in accordance with the following laws:—

Law I.—If we have the linear triads $ap.b$ and $cp.d$, a statement q exists such that we have the linear triads $ad.q$ and $bc.q$.

Law II.—If we have the linear triads $ab.p$ and $cp.d$, a statement q exists such that we have the linear triads $aq.d$ and $bc.q$.

Law III.—If we have the linear triad $ab.c$, and a and b are equivalent statements, all the three statements a, b, c are equivalent.

Law IV.—If a and b are equivalent, we have the linear triads $ac.b$ and $bc.a$, whatever statement c may be.

Law V.—No statement is absent from the system whose presence is consistent with the foregoing laws.

The distribution through a system of statements of the triads of the two species in accordance with the foregoing laws completely defines the system as one possessing all those properties of statements which are really under consideration by the logician when studying the relations of statements to each other. The fact that the extreme statements of a linear triad cannot be regarded as equivalent without also regarding the mean statement as equivalent to them is a necessary consequence of Law III.; and thus all that is essential in a system of statements, so far as the exact thought of the formal logician is concerned, is that it is a system of entities, pairs and triads of which are of different sorts, and are distributed through the system in accordance with the specified laws.

This uniform distribution of pairs and triads of statements involves of course a similar regularity of distribution of distinguished and undistinguished collections of larger numbers of statements, and also of the aspects of those collections; and consequently a system of statements possesses "form," and owes its properties to the possession of this "form," in precisely the same way as a system of points does. Thus in the case of the logical theory of statements, as in that of the geometrical theory of points, it is "form" as here defined which is the real subject-matter of exact thought.

A remarkable circumstance connected with the laws defining the "form" of a system of points, and that of a system of statements, will no doubt have already been noticed. If we exclude Law V. of the former set of laws, the two sets of laws are the same; and it is thus on this Law V., and that only, that the differences between the properties of the two systems depend. This Law V. is that which expresses the fact that two straight lines can only cut once; so that, if in geometry this restriction were removed, the study of points would in all that is essential be the same thing as the study of statements. I cannot pursue this very interesting fact any further here; but it will now be understood why the expression "linear" has been used with reference to certain triads of statements.

As the views here put forward as to the true nature of the subject-matter of the exact thought of the logician in his consideration of the mutual relations of statements are somewhat novel, I cannot well pass on with the observation that the rest is mere matter of detail, but must briefly allude to one or two matters of importance. And first let us consider those relations which are usually considered as relations between *two* statements, but are, as I have already said, really relations between *three* statements, one of which is a truism or a falsism.

In a linear triad, let the mean statement be a falsism, then the extremes cannot both be regarded as true. For to regard them both as true is to regard them as both equivalent to a truism, *i.e.* as equivalent to each other. But if they are equivalent they must be equivalent to the mean statement, which is a falsism, *i.e.* they must be false and not true. The two extremes are here, therefore, *contrary* or *inconsistent*.

If we take the mean statement of a linear triad to be a truism, then the extremes cannot both be regarded as false, they are *subcontrary*.

If we take one of the extremes to be a truism, then, if the other extreme is regarded as true, the mean must also be so regarded. Here the two latter statements are *subalterns*, the extreme being the *subalternant*, and the mean the *subalternate*. In common parlance the former statement "implies" the latter.

Next let me point to one instance in which certain relations of statements to each other involve others. If we have the linear triads $ab.c$ and $bc.d$, it can be shown to be an immediate consequence of the laws which I have given as defining the "form" of a system of statements, that we have also $ab.d$ and $ad.c$. Taking, then, b to be a truism, this becomes:—If the statement a implies the statement c, and the statement c implies the statement d, then the statement a implies the statement d, and $ad.c$ is a linear triad. Observe here that the last part of the conclusion is not usually pointed out, because the fundamental character of the linear triad has not been noticed.

I proceed finally to consider the use of the words "and" and "or," and the logical relation of statements such as "a and b," "a or b," to the statements a, b. If a, b, c be any three statements whatever, there exists a statement x, which is such that the three triads

$$ab.x,\ bc.x,\ ca.x$$

are all linear triads. This statement x is uniquely related to the triad a, b, c; that is, it is a necessary consequence of the laws defining the system that, if any other statement, y, is such that the triads

$$ab.y,\ bc.y,\ ca.y$$

are all linear triads, then the statements x and y are equivalent. This statement, x, I term the *symmetrical resultant* of the triad a, b, c.

Now let t be a truism, and f a falsism. Then the symmetrical resultant of the triad a, b, f is the statement usually written

"a and b,"

and the symmetrical resultant of the triad a, b, t is the statement usually written

"a or b,"

where, however, the "or" would be more properly written "$\frac{\text{and}}{\text{or}}$," as in mercantile documents.

In the general case, in which we take any three statements, a, b, c, without taking one of them to be necessarily either a truism or a falsism, the symmetrical resultant will be

"a and b, or b and c, or c and a,"

or

"a or b, and b or c, and c or a,"

the two statements being equivalent. These statements have tacit reference to a truism and a falsism, as they are expressed in terms of the statements "a and b," "a or b," &c., which are, as we have seen, symmetrical resultants of the triads a, b, t, and a, b, f, &c. But no truism or falsism is really involved in arriving at the symmetrical resultant of a, b, c; it is a function of a, b, and c, only. As, however, there is no simpler verbal expression for the symmetrical resultant in vogue, we are obliged to have recourse to one which expresses it by tacit reference to statements which are not really involved; just as, in the algebraic treatment of geometry, the relations of points to each other are expressed by means of an algebra which has tacit reference to an "origin" and "axes," which are not really involved in the relations which are represented.

I now pass away from the special consideration o statements.

The principles which I have enunciated in the case of points and statements may readily be shown to extend to entities of other descriptions. Thus, straight lines, curves, surfaces, &c., as individuals are mere entities, just as points are. Some are undistinguished from each other, and some are distinguished; thus one plane is exactly like another, but is distinguished from a straight line. These various entities owe their properties to the fact that they bear various relations to each other, and to points. The relations which they bear to each other are defined when we know those which they bear to points; and the relations which they bear to points are due simply to the fact that some points lie on them, and others do not. That a point does or does not "lie on" a curve is not, however, of itself a material circumstance; it is accidental clothing. All that is material to the geometrician is, that the pair of entities consisting of a curve and a point which lies on it is distinguished from the pair which consists of that curve and a point which does not lie on it, and that the two sorts of pairs are distributed through the whole system of points and curves in a definite way. Though the relations of these other geometrical entities to each other may be arrived at by considering the relations which they bear to points, we may of course consider their relations without reference to points. Thus the system which consists wholly of straight lines is one composed of entities which are undistinguished from each other, and are such that pairs of those entities are of two sorts, viz. two straight lines cut or do not cut each other; and these two sorts of pairs are distributed through the system in accordance with definite laws.

Such considerations as these apply, not merely to straight lines, curves, surfaces, &c., but to all other entities which are dealt with by the geometrician. Vectors, quaternions, matrices, and even algebras, are as individuals all mere entities, and owe their properties to the fact that they bear certain relations to the entities previously referred to, and to each other; and all that is essential in these relations depends merely on the fact that certain individuals, pairs, triads, &c., and aspects of these, are distinguished from each other, and certain undistinguished, and have a specific distribution. Here therefore, also, it is "form" in the sense in which I have defined that word, and "form" only, which is under consideration.

In the same way terms, classes, syllogisms, and other logical conceptions are all mere entities; and all that is essential in their properties, so far as the exact thought of the formal logician is concerned, depends upon the fact that they compose systems possessing "form," *i.e.* a definite distribution of distinguished and undistinguished collections of entities, and of aspects of those collections.

A system of entities under consideration in any investigation will usually comprise entities of many sorts, some of which are taken into account merely for the purpose of facilitating the study of the properties of others. Algebras, and operations such as quaternions, are examples of entities thus added by the geometrician to a system of points, lines, curves, &c., in order to aid in arriving at the properties of the latter. By thus adding "auxiliary" entities to a system, we may also greatly simplify the definition of its "form"; so that a system which would otherwise be defined only by reference to the distribution of aspects, or of collections of a large number of entities, can be defined by definitions which refer merely to the distribution of collections of a small number of entities, and make no allusion to aspects. In fact, it may be shown that, by the addition of suitable entities, the "form" of any system of entities whatever may be defined by specifying merely that certain *individual* entities, and certain *pairs* of those entities, are like and certain unlike.

The light which is thrown by the foregoing investigations will, I hope, be sufficient to insure the appreciation, if not the acceptance, of the following general definition of the subject-matter of exact thought:—

Whatever may be the true nature of things, and of the conceptions which we have of them (into which points we are not here concerned to inquire), in the operations of exact thought they are dealt with as a number of separate entities.

Every entity is distinguished from certain entities, and (unless unique) is undistinguished from others. In like manner every collection of entities is distinguished from certain collections of entities, and (unless unique) is undistinguished from others; and every aspect of a collection of entities is distinguished from certain aspects of collections, and (unless unique) is undistinguished from others.

Every system of entities has a definite "form," due (1) to the number of its component entities, and (2) to the way in which the distinguished and undistinguished entities, collections of entities, and aspects of collections of entities, are distributed through the system.

The peculiarities and properties of a system of entities depend, so far as the processes of exact thought are concerned, upon the particular "form" it assumes, and are independent of anything else.

It may seem in some cases that other considerations are involved besides "form"; but it will be found on investigation that the introduction of such considerations involves also the introduction of fresh entities, and then we have merely to consider the "form" of the enlarged system.

If the definition of the subject-matter of exact thought which I have thus ventured to formulate be an accurate one, it will be obvious that there are divisions at present maintained between different branches of exact science which must be regarded as unnecessary and arbitrary; the only differences which should be treated as material being such as are due to differences of "form." These differences are certainly not such as to justify the isolation and separate study of individual systems, without any attempt to fix the position which each holds in the general body of possible systems, or to ascertain the exact points in which each resembles or differs from other systems of the whole body. The scientific study of each system must involve that of the properties common to all, of the general laws regulating the distribution of distinguished and undistinguished collections and aspects of collections in systems of any "form," and of the possibilities of variety in their "forms."

A. B. Kempe.

NOTES.

The retirement of Sir Gabriel Stokes from the Presidency of the Royal Society is to be taken as an occasion for the expression of the Fellows' high appreciation of his services. He has held office, either as one of the secretaries or as president, for thirty-six consecutive years; and it is unnecessary to say how much the Royal Society has benefited by his labours during that long period. It is thought that the most suitable way of marking the present occasion would be to obtain a good portrait of Sir Gabriel for the gallery of the Society; and an influential committee has been appointed to make the necessary arrangements.

At a meeting of the City side of the Gresham Committee at Mercers' Hall on Monday, Mr. Karl Pearson, Professor of Mechanics and Applied Mathematics in University College, was elected Gresham Lecturer in Geometry, in succession to the Dean of Exeter.

Dr. J. Jagor, the eminent ethnographical traveller, intends to make a scientific tour in British India. Remembering his researches forty years ago, many men of science in Berlin take much interest in his present plans.

The German Colonial Society have forwarded a number of books on tropical plants to Emin Pasha to further his scientific researches, as he lately complained (in a letter to Prof. Schweinfurth) of his want of works of reference. Prof. Noack has lately received a letter from the Pasha, dated Tabora, the middle of August. He then intended to leave for Uramba in four or five days, on his way to Lake Tanganyika.

At a meeting of the Royal Botanic Society on Saturday, the Secretary answered various questions as to the destructive action of fogs on plants. He said it was most felt by those tropical plants in the Society's houses of which the natural habitat was one exposed to sunshine. Plants growing in forests or under tree shade did not so directly feel the want of light; but then, again, a London or town fog not only shaded the plants, but contained smoke, sulphur, and other deleterious agents, which were perhaps as deadly to vegetable vitality as absence of light. Soft, tender-leaved plants, and aquatics, such as the *Victoria regia*, suffered more from fog than any class of plants he knew.

On Monday, Mr. T. G. Pinches read a paper before the Royal Asiatic Society, on the newly-discovered version of the story of the creation. He had had the good fortune, in the course of his investigations into the contents of the unregistered tablets in the British Museum, to find in one of them, brought home by Mr. Rassam in 1882, a still earlier version than that which the late Mr. George Smith had translated. It was a bilingual tablet, the text being Akkadian, and the gloss Assyrian; and while the date of the tablet itself was, like the rest of those in Assur-bani-pal's library, not older probably than 650 B.C., the Akkadian text was, in his opinion, an exact copy of an older document, which had, in all probability, been put into its present shape 3000 B.C., or even earlier. One side, the obverse, is devoted to the creation story. The other, the reverse, is simply an incantation form for the purification of the great temple tower E-zida, now so well known as the mound called Birs-Nimrud. The text might be roughly divided into three paragraphs or sections of about ten lines each. The first describes the time when nothing was, neither "the glorious house of the gods," nor plants, nor trees, nor cities, nor houses, no, not even the abyss (Hades) nor Eridu (regarded by the author as Paradise). The second section describes the making of Paradise with its temple tower E-Sagila, founded within the abyss. Then was Babylon made, and the gods, and the land, and the heavens, and mankind. The third section then proclaims the creation of animals, plants, and trees (in that order), of the Tigris and of the Euphrates. The fourth records the building of cities and houses. Of all except the last, Merodach, the god, seems to be the active creator, and he is also to be understood as the builder, through men, of the cities, &c. Mr. Pinches pointed out several interesting words and forms occurring in this oldest form of the creation account, which had subsequently assumed so many diverging shapes. A discussion followed, more especially on the word Adam, rendered by Mr. Pinches "foundations" (of earth), but by Dr. Zimmern "living things." This was probably the origin of the Hebrew word Adam.

According to the *Journal de la Chambre de Commerce de Constantinople*, the greatest electric project which has yet been suggested is being planned—the construction of a line from St. Petersburg to Archangel. The electric current would be supplied by a series of generating stations distributed along the line. It is estimated that the cost, including the rolling stock, would be 46,509 francs per kilometre.

The forty-first volume of the *Izvestia* of the Moscow Society of Friends of Natural Science contains a valuable review of the work done in zoology, anatomy, and embryology in connection with the Society during the last twenty-five years.

Natural History and Ethnographical Museums have been opened lately in several towns of East Siberia; and a like institution has now been established at Tobolsk. It contains most valuable ethnographical collections to illustrate the life of the Ostyaks and the Samoyedes, as also a very complete herbarium of the Tobolsk flora, and a collection of books, pamphlets, &c., on the region.

At a recent meeting of the Paris Academy of Medicine, M. Motais, of Angers, maintained that myopia, or short-sightedness, is one of the products of civilization. An unexpected proof of this view was found in the condition of the eyes of wild beasts, such as tigers, lions, &c. M. Motais, having examined their eyes by means of the ophthalmoscope, discovered that animals captured after the age of 6 or 8 months are, and remain, hypermetropic, while those who are captured earlier, or, better still, are born in captivity, are myopic. This short-sightedness is evidently induced by artificial conditions of life.

M. A. Berthoule has contributed to the *Revue des Sciences Naturelles Appliquées* a series of papers, well illustrated, on the lakes of the Auvergne region, and their fauna, natural or introduced. He considers that new species might be placed in many of these lakes, and, if properly attended to, would yield large profits to pisciculturists.

The curious idea of preserving dead bodies by a galvanoplastic method is not new, but we note that a Frenchman, Dr. Variot, has been lately giving his attention to it (*La Nature*). To facilitate adherence of the metallic deposit, he paints the skin with a concentrated solution of nitrate of silver, and reduces this with vapours of white phosphorus dissolved in sulphide of carbon, the skin being thus rendered dark and shiny. The body is then ready for the electric bath, which is served by a thermo-electric battery, giving a regular adherent deposit of copper if the current is properly regulated. With a layer of ¼ to ¾ mm. the envelope is solid enough to resist pressure or shock. Dr. Variot further incinerates the metallic mummy, leaving holes for the escape of gases. The corpse disappears, and a faithful image or statue remains.

Mr. Nathaniel Waterall, Waddon, Croydon, writes to us that, in one of the outhouses in the garden belonging to the house in which he resides, a robin's nest was found some time ago in a flat hand-basket, hanging on the side of the wall. In the nest there were four young ones, recently hatched. They were allowed to remain until their time came to fly away. The basket had been in the same position for a considerable time.

Prof. E. A. Kirkpatrick contributes to the *Evening Gazette* (Mass., U.S.), a paper in which he shows how parents —mothers especially—might do good service to psychology by recording "certain facts of child development." He suggests that they should devote particular attention to the growth of the power of speech. They ought, he thinks, to keep two lists of words—one containing all words articulated by the child, with indications as to how they are pronounced; the other, all words used "understandingly." The first list would indicate the common difficulties encountered in learning to articulate, and an examination of a sufficient number might make it possible to determine whether there really are "general laws of mispronunciation." The second list would show the intellectual progress of the child as it learns new words, and learns to use old ones with increasing accuracy, and to put them together into phrases and sentences. Words that are invented by the child, and those used in a sense different from the ordinary meaning, are especially interesting, and throw considerable light on the subject of how children classify and generalize. Prof. Kirkpatrick proposes that separate sheets shall be kept for each week, or perhaps for each month in the case of the articulating vocabulary. No confusion will then result, and on the back of the sheets may be given the peculiar meanings attached to words, the earlier attempts at putting words together, the later sentences of interest, especially those showing the characteristic grammatical errors, and other items. He is of opinion that the comparison of a number of such vocabularies would help to solve several interesting problems; and he expresses a hope that those who have begun, or think of beginning, the preparation of lists will send him the record for several months, before the middle of next May. Anything of scientific value that may be thus reached will be published, and along with it will be given "the names of those by whose patient observation it has been obtained."

Prof. Brückner, of Berne, has recently called attention to the existence of climatological periods of about 35 years for the whole globe (more marked in the interior of continents). The years 1700, 1740, 1780, 1815, 1850, and 1880 appear as centres of cold, wet periods; while the years 1720, 1760, 1795, 1830, and 1860 are centres of warm, dry periods. During the warm periods the passage of oceanic air to the continent has been hindered, and during the cold it has been favoured, increased rainfall occurring in the latter case.

IT is stated that another meteorological station has just been added to the list of those in telegraphic communication with the Observatory at Si-ka-wei near Shanghai—namely, at Tientsin. M. Chapsal, whose services in promoting and improving the present system of semaphore signalling and meteorological observations are deserving of great praise, requested M. Ristelhueber, the French Consul-General at Tientsin, to use his influence with the Director-General of Chinese Telegraphs, to procure the free transmission of the necessary telegrams, with the result that permission has been obtained. The observations at Tientsin, made by Mr. Bellingham, will probably be of much value.

WE have received a small pocket-book, published by Alfred Watkins, Hereford, on exposure notes, for use with the Watkins exposure meter. This meter seems to be of a very ingenious construction, and, according to the accounts we have read about it, should be found a very serviceable appendage to the photographic kit. The instrument is very neat and compact, being only $2\frac{1}{2}$ inches long and $1\frac{3}{4}$ inches in diameter, and consists of a combination of a bromide of silver actinometer, a chain pendulum for timing the exposure, and a set of calculating rings, each carrying a pointer. If each of these rings be set for the correct value of the factors indicated, a fifth pointer automatically indicates the correct time of exposure in seconds or in fractions of a second, as the case may be. In this note-book, full instructions are given as to the method of using it, followed by 60 pages in which notes on exposure, values of the factors, and other details may be inserted. In addition to the above, at the end are inserted various hints and jottings which should be found useful to the many photographers, both amateur and professional, who will use this note-book.

THE Belgian Consul-General at Singapore, in a report quoted in the new number of the *Board of Trade Journal*, says that rubies and sapphires abound in the Siamese provinces of Chantaboun and Battambang. Several mines have been worked since a remote period by the natives, but for a long time they produced for the most part only stones of little value. It was in 1874 that the first mine of sapphires of good quality was discovered by a native huntsman in the environs of Chantaboun. The place was very difficult of access, so that the news of the discovery spread slowly. Rangoon being still at that time the nearest market to Siam for the sale of precious stones, the Burmans were the first to know of the existence of the new mine by the stones which were offered for sale at Rangoon. Some went there, and the large sums which they brought on their return from the sale of their produce brought about a movement of very active emigration for the same destination during the years 1878 and 1879. The new-comers discovered several mines as rich as the first. But there, as at Bantaphan, fevers made such sad ravages in the ranks ef the workers, that in 1880 the number of arrivals decreased in considerable proportions, and at the present time the population of these mines, which once reached the figure of 10,000, consists of a few Pegu Toung-Thons, who can ward off better than other races the ills resulting from the terrible climate of the country. Rubies, onyx, and jades are also found in considerable quantities in the province of Chantaboun, but their quality leaves much to be desired. Battambang is as rich in precious stones as Chantaboun, and it is stated that recently diamonds have been found near the frontier of Cambodia; but the mines of this province are almost abandoned because of the insalubrity of the climate, and the want of protection for foreign workers.

THE canalization of the immense marshes of Pinsk, in West Russia, is rapidly going on. No less than 185 square miles of marshes have been drained on the banks of the Pripet, and more than 7,000,000 acres of meadow-land have been reclaimed in this way. Forests which formerly remained inaccessible and valueless, are now easy of access, and begin to be profitable.

A SERIES of experiments upon the synthetical production of cyanogen compounds by the mutual action of charcoal, gaseous nitrogen, and alkaline oxides or carbonates, at high temperatures and under great pressure, are described by Prof. Hempel in the new number of the *Berichte*. Bunsen and Playfair long ago showed that when charcoal and potassium carbonate are heated to redness in an atmosphere of nitrogen, a certain quantity of cyanide of potassium is formed. Since that time Margueritte and Sourdeval have further shown that barium carbonate may be used in place of the potash, and that the barium cyanide produced may be again decomposed by steam into ammonia and barium carbonate. These reactions afforded a theoretically continuous process for the conversion of atmospheric nitrogen into ammonia, a process which, if it could only be worked on the large scale, would doubtless be of immense value. Unfortunately, however, only small proportions of the substances appear to enter into the reaction at ordinary pressures, hence the yield is not sufficiently large to render the process economical. Prof. Hempel, however, by means of a simple pressure apparatus, has shown that the reaction is very much more complete, and when potash is used very energetic, under the pressure of sixty atmospheres. His apparatus consists of a strong cylinder closed at one end, and worked out of a single block of steel. The steel top screws tightly down, so as to form a closed chamber, and is pierced with two apertures—one for connection with the compressing-pumps, and a second to admit the passage of an insulated copper rod. Within the steel cylinder is placed a smaller cylinder of porcelain, in which the mixture of the alkaline oxide or carbonate and charcoal is placed. Through the centre of this mixture passes a rod of charcoal, which is connected above with the copper rod and below with the steel cylinder itself, in such a manner that when the wires from a strong battery or dynamo are connected with the projecting end of the copper rod and the exterior of the steel cylinder respectively, the rod of charcoal becomes heated to redness. The pumps are then caused to force in nitrogen gas until the desired pressure is registered on the gauge. Experimenting in this manner it was found that the amount of barium cyanide formed in fifteen minutes under a pressure of sixty atmospheres was nearly four times that formed at ordinary atmospheric pressure; while in case of potassium carbonate the reaction was so energetic that in a few seconds the heated carbon rod itself was dissolved. Hence it is evident that the formation of cyanides by heating together alkaline carbonates and charcoal in an atmosphere of nitrogen is greatly accelerated by largely increasing the pressure under which the reaction occurs.

THE additions to the Zoological Society's Gardens during the past week include a Cape Hyrax (*Hyrax capensis*), an Areolated Tortoise (*Homopus areolatus*), a Galeated Pentonyx (*Pelomedusa galeata*), two Rough-scaled Lizards (*Zonurus cordylus*), six Dwarf Chameleons (*Chamæleon pumilus*), two Rufescent Snakes (*Leptodira rufescens*), three Smooth-bellied Snakes (*Homolosoma lutrix*), a Rufous Snake (*Ablabes rufulus*), a Ring-hals Snake (*Sepedon hæmachates*), a Robben Island Snake (*Coronella phocarum*), from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; a Common Fox (*Canis vulpes* ♂), British, presented by Mr. C. T. Stanhope Bilbrough; a Demoiselle Crane (*Grus virgo*) from North Africa, presented by Mrs. Wright; two Cactus Conures (*Conurus cactorum*) from Brazil, presented by Mr. H. C. Martin; two Common Mynahs (*Acridotheres tristis*) from India, presented by Mr. G. W. Blathwayt; two Snow Buntings (*Plectrophanes nivalis*), three Bramblings (*Fringilla montifringilla*), British, presented by Mr. J. E. Baldwin; a Broad-fronted Crocodile (*Crocodilus frontatus*) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

VARIATIONS OF CERTAIN STELLAR SPECTRA.—The November number of the *Monthly Notices of the Royal Astronomical Society* contains a note by the Rev. T. E. Espin, "On the Variation of the Spectra of R Coronæ and R Scuti, and on the Spectra of R Aurigæ and R Andromedæ." The following are the observations recorded:—

R Coronæ.

1890 March 26.—Star about 5·8 mag. Colour yellowish-white. Nothing certain seen; sometimes irregularities, either dark or bright lines suspected.

1890 April 10.—Continuous spectrum, but again suspected lines; one bright one strongly suspected near the place of F, but believed more refrangible.

1890 September 8.—A most wonderful change has taken place in this star's spectrum. Two large absorption bands have appeared, one in the bluish-green, and one in the bluish-violet. These bands are sharply defined on the least refrangible side. Bringing the spectrum to a line, bright patches were seen far away in the violet—these may be bright lines or bright spaces. The star is now pale yellow. The magnitude still about 6.

1890 September 14.—The spectrum is apparently of the IV. type [Group VI.] since the bands fade away on the more refrangible side, but are sharply defined on the less refrangible. The band in the bluish-green was thought to be occasionally resolved into fine lines; between the two bands a bright line was suspected. The star is of the same magnitude, and now pale orange.

1890 October 8.—The star is only dim, but the bands seem to have faded.

1890 October 10.—The star has now nearly returned to the continuous first type spectrum observed in the spring. The big band in the bluish-green has disappeared, but the band in the violet is probably there still, but faint. The bright line previously mentioned again suspected. The star is now yellowish-white, and the magnitude about the same.

R Scuti.

1890 August 21.—III. Type (= Group II.). Bands 1, 2, 3 of Dunér's nomenclature seen, and also 7 and 8, which are the strongest.

1890 August 23.—Estimated 7·2 mag.; pale orange-red; carefully examined. Type III., but peculiar. The usual bands 1, 2, 3, seen; the bands 4 and 5 faint; 7 and 8 are strong. Bringing the spectrum to a line, bright knots seen in the violet and ultra-violet, either lines or spaces.

1890 September 8.—Bands 4 and 5 much better seen, but the other bands remain the same. The star is now brighter.

1890 October 10.—The star is now about 6 mag. The III. type spectrum is no longer certainly seen. A remnant of band 7 still remains; the others have almost, if not quite, disappeared. Perhaps 8 is there.

1890 October 12.—The star about 6 mag. Type doubtful; possibly III., but very indistinct.

1890 October 15.—The star is about 6·5. The spectrum is again clearly III. type. Bands 7 and 8 best seen; also 1 to 4 visible. The bands are, however, faint and dim, but are larger now, and the spectrum is similar to that observed on August 21.

1890 November 1.—Normal III. type, and about 6·8 mag. The bands are well seen in all parts of the spectrum. Bands 7 and 8 are especially broad.

R Aurigæ.

1890 August 18.—Mag. 7·2; colour fine rose-red. Very fine III. type, and the spectrum appears to resemble that of Mira rather than that of R Andromedæ.

R Andromedæ.

1890 August 23.—Mag. 7·3 ±. Bands not deep except in the blue and violet. Bringing the spectrum to a line, several bright lines in the violet and ultra-violet suspected. F possibly bright.

1890 September 8.—The star has increased in light, and γ hydrogen and F certainly seen, but still faint.

1890 September 14.—Bands in the red well seen, the yellow bands faint. F very plain now.

1890 September 15.—The F line now a wonderful spectacle. The star is not so red, the bands are generally faint, except in the red. A bright space in the yellow looks like a mass of fine bright lines. A deep band in the violet—$H\gamma$ and D_3—possibly bright.

BRITISH ASTRONOMICAL ASSOCIATION.—The first number of the Journal of this Association has been recently issued. Miss A. M. Clerke has contributed a paper on the rotation periods of Mercury and Venus, in which she brings forward the evidence which led Schiaparelli to the conclusion that their rotation period is the same as their sidereal period of revolution around the sun. Another paper, by the editor, Mr. E. Walter Maunder, entitled "The Chief Nebular Line," deals with the character and position of the chief line seen in the spectrum of the nebulæ, and its probable origin. Beginning with Dr. Huggins's discovery, in 1864, of the character of nebular spectra, it is shown how he suggested that the brightest line was due to an unknown form of nitrogen. This view was widely taught until 1887, when Prof. Lockyer enunciated the principles of his meteoritic hypothesis, and testified to the coincidence of the line with the remnant of the brightest magnesium fluting at λ 5006·5—a statement combated by the later observations of Dr. and Mrs. Huggins. Mr. Keeler's observations of nebular spectra, made at the Lick Observatory with a Rowland grating having 14,438 lines to the inch, demonstrate that the nebular line may appear both *more* and *less* refrangible than the brightest edge of the magnesium fluting. This being so, Mr. Maunder concludes "that we do not know the position of the nebular line with sufficient accuracy to say positively that it does or does not accord with the magnesium fluting." The Journal is supplied free to members of the Association.

ELEMENTS AND EPHEMERIS OF ZONA'S COMET (*e* 1890).—A Royal Astronomical Society circular contains the following elements and ephemeris computed by Dr. Hind. The orbit depends upon an observation at Rome on November 16, one by Baron von Engelhardt on the 18th, and the Paris observations of the 21st.

Perihelion passage, 1890 August 8·43592 G.M.T.

		°	′	″	
Longitude of perihelion (π)	...	113	16	52·1	Appt.
,, ,, ascending node (☊)		85	25	2·7	Eq.
Inclination (*i*)	... ...	25	38	57·4	Nov. 20.

Perihelion distance, 2·0597 (Earth's mean distance = 1).
The motion of the comet is retrograde.

Ephemeris for Greenwich Midnight.

1890.		R.A. h. m. s.		Decl. ° ′		Distance in Terms of the Earth's Mean Distance from the Sun.
Dec. 18	...	2 42 0	...	+32 19·9	...	1·757
,, 20	...	2 35 4	...	31 53·6		
,, 22	...	2 28 38	...	31 27·4	...	1·844
,, 24	...	2 22 42	...	31 1·5		
,, 26	...	2 17 14	...	30 36·0	...	1·937

The comet is, therefore, still in Perseus, and moving towards Triangulum. The sidereal time at Greenwich at 10 p.m., on December 18 = 3h. 49m. 50s. The intensity of light on December 26 = 0·47, that on November 16, the date of discovery, being taken as unity.

CHEMICAL ACTION AND THE CONSERVATION OF ENERGY.

THE conservation of energy is accepted as a general principle without question, but its operation is often so disguised, especially in chemical changes, that it is not apparent to a superficial observer, and, as a consequence, it is too often treated as a dead letter.

This is largely due to the enunciations given by thermochemists, who attempt to draw an impossible distinction between chemical and physical changes, and imply that the latter are not subservient to the law of the conservation of energy. The accepted principles of dissociation, together with the recognition of the complex nature of liquid molecules, and of the existence of compounds in solution, gives us, however, the means of explaining *all* the thermal results of any action in accordance with the recognized principles of science (see Chem. Soc. Trans., 1889, 14).

Chemical affinity, or the potential energy possessed by atoms, becomes satisfied to a greater or less extent when these atoms combine together, and a corresponding amount of kinetic energy must be developed. In all ordinary calorimetric operations this kinetic energy takes the form of heat. An "endothermic" compound is, therefore, an impossibility, if the term be used in the sense of a "body formed from its constituent *atoms* with absorption of heat."

The same principle which governs atomic combinations must also govern those complex reactions with which we generally deal. They occur in order to satisfy affinity—in order to convert potential into kinetic energy—and heat *must*, therefore, be liberated during them. If any absorption of heat does occur, it can only be due to some secondary decomposition, which has followed the primary heat-evolving action, owing to the alteration in conditions occasioned by this action. Dissociation affords a simple explanation of the occurrence of such secondary decompositions.

Just as a certain temperature must be attained before any particular combination can occur, so there is a certain temperature above which any particular compound cannot exist; but, owing to the molecules in a mass of fluid being at different temperatures, dissociation begins when the average temperature of the mass is below this point, and is not complete till the average temperature is considerably above it. The stable condition of a fluid at any temperature between these limits is such that there are $\frac{1}{x}$th of the total molecules dissociated: if this condition be disturbed by the removal of any of the dissociation products, other molecules will have to dissociate in order to reproduce it.

The effect of dissociation on the thermal value of any change may be illustrated by the case of carbon dioxide and carbon, which react at 600° to produce carbon protoxide with an absorption of 39,000 cal. At 600° carbon dioxide is partially dissociated, and consists of $xCO_2 + (1 - x)CO + (1 + x)\frac{1}{2}O_2$. With the free oxygen in this mixture the carbon can combine, *evolving* 29,000 cal.; and more of the carbon dioxide must then dissociate to reproduce the stable condition; this dissociation absorbs 68,000, leaving 39,000 cal. as the algebraic sum of the combination and consequent decomposition.

Nearly every series of reactions in which heat is absorbed can, I believe, be fully explained by one of the reagents being to start with in a state of partial dissociation,[1] and in the remaining few a similar explanation is obtained in the dissociation of the product of the reaction.

An exothermic reaction cannot possibly be impeded by the fact that its occurrence will *subsequently* involve a greater absorption of heat. The carbon cannot be supposed to refrain from combining with the free oxygen by the fact that its doing so will disturb the equilibrium of the mass and necessitate the decomposition of other CO_2 molecules. To imagine that it would do so, would be to endow the atoms with intelligence.

The converse fallacy is often held—that an endothermic reaction may occur if it forms part of a cycle of which the final result is an evolution of heat. This is obviously impossible. Unless we endow the molecules with prescience, we can no more imagine that they will react at first so as to increase their stock of potential energy (absorb heat) in order that this stock may subsequently be diminished by the interaction of the bodies first formed, than we can imagine that a stone will roll of its own accord a short way up a hill in order to have a long roll down on the opposite side.

A considerable amount of misconception also exists as to the influence of heat in effecting endothermic reactions. No amount of heating can make an endothermic reaction possible so long as it remains endothermic; but it is, of course, quite possible that a reaction, which would be endothermic at one temperature, may, owing to the relative magnitude of the heat capacities of the reagents, become exothermic at another; or that heating the reagents may induce dissociation, and that the new reagents thus introduced may render an action possible which was impossible with the original reagents.

Another not uncommon error is to imagine that an endothermic reaction may be brought about by the simultaneous occurrence of some independent reaction evolving heat. If the second reaction is really independent of the first, it cannot possibly have any influence on it; the heat liberated during it will be no more capable of rendering the endothermic reaction possible than heat supplied from any other source. Cases in which the contrary appears to take place may be explained either by the formation of new reagents during the exothermic action, or by the previous combination of the body; which reacts exothermically with that which could by itself react endothermically only.

Endothermic changes in which one or more of the reagents is a gas either do not occur directly, or, in the one or two cases where they do so, the thermal value of the reaction at the temperature of its occurrence is not known, or else the results may be easily explained in the same way as in the case of the reaction between carbon and carbon dioxide. The reactions which present serious difficulties are those where one or more of the reagents is liquid, such as (1) the dissolution of a solid in a liquid; (2) the dilution of a strong solution; (3) double decomposition between two substances in solution.

The heat absorbed when a solid salt is dissolved in a solvent—water, for example—must be attributed, not merely to the fusion, but also to the volatilization of the salt, and would amount to 5000 to 15,000 cal. per gram-molecule. To bring this about, some affinity must be brought into play capable of developing more than this amount of heat. Now, the satisfaction of the affinity of a large proportion of water for the salt molecule present develops less—the heat of dissolution is a negative quantity; but the water consists of aggregates of the fundamental molecules in a state of partial dissociation; and, from the fact that water will give off its fundamental molecules (*i.e.* has a vapour tension) at ordinary temperatures, we must conclude, I think, that this dissociation extends so far that some of the fundamental molecules themselves are present. To convert a mass of water at ordinary temperatures into its fundamental molecules (into gas), requires an absorption of 10,000 cal. per H_2O, so that those fundamental molecules must possess an amount of potential energy equivalent to 10,000 cal. more than that possessed by the average aggregate: they would, consequently, be capable of combining with a salt molecule and evolving 10,000 cal. more per H_2O than the average aggregate would, and they would be capable of effecting a combination which the average aggregate could not. The combination of one, or at most two, such fundamental molecules with a salt molecule would evolve more heat than that absorbed in the separation of the salt molecule from its fellows: we have, therefore, the conditions necessary for a possible reaction—a primary action *evolving* heat. The removal of the fundamental water molecules would necessitate the dissociation of other aggregates to supply their place, and these, in their turn, would combine with the salt hydrate present till the highest hydrate capable of existing under the circumstances was formed. The heat absorbed in the decomposition of the water aggregates is, however, nearly entirely counterbalanced by the recombination of the water molecules with each other after they have combined with the salt, for there is independent evidence to show that the water molecules present in a very complex hydrate are as much combined with each other as they are in the aggregates of pure water: thus, the net result obtained, when dissolution is complete, is simply the algebraic sum of two quantities: (1) the heat evolved in the combination of the salt with the water aggregates, (2) the heat absorbed in volatilizing the salt; and, according as the former or latter of these is the greater, so will the heat of dissolution be positive or negative; but the motive power, if I may use such a term, which produces these results is the potential energy possessed by the free water molecules, an energy which enables them to overcome the affinity of the salt molecules for each other, and produce a primary heat-evolving reaction.

The second case in which heat is absorbed by the dilution of a strong solution occurs as a part of the process of the dissolution of a solid salt, and is comprised in the above explanation.

Cases of double decomposition in which heat is absorbed would require too long an explanation for insertion here, and reference must be made to my former communication on this subject: it will suffice to say that they can in all cases be explained in accordance with the principle of there being a primary exothermic reaction, by recognizing the presence of several hydrates of various degrees of complexity, the less complex of these bringing about this primary reaction, and its removal necessitating as a consequence the endothermic decomposition of the higher hydrates to supply its place.

If the three conditions necessary to render a reaction possible exist—(1) a certain proximity of the reagents, (2) a certain affinity, *i.e.* power of developing heat by their reaction,

[1] The amount of dissociation necessary is almost infinitesimal, and may often be too small to be recognized by other means.

(3) a temperature within certain fixed limits—it follows that the reaction in question must occur; for, if it did not, the atoms would be in a state of strain inconsistent with stability; it would be as if a stone did not fall to the earth when there was nothing to prevent its falling. As a consequence of this, it follows that, in any complex system of atoms, where two or more different arrangements are independently possible, and where the various products remain within the sphere of action, and are capable of further interaction, then, those products, the formation of which is attended with the greater evolution of heat, will be formed to the exclusion of the others; or, if the two actions develop the same amount of heat, they will both occur to an equal extent.

I showed that the division of a base between two acids takes place entirely in accordance with this principle; wherever the salt formed remains undissociated in the liquid, the base is divided equally between the two acids, because the heat of neutralization of all such acids is the same, whereas, in other cases, where one of the salts formed is stable, and the other is in a state of partial dissociation, the undissociated salt is formed to the exclusion of the dissociated one; such small divergencies from this rule as are observed being due to the solutions examined being considerably stronger than they should have been, the heat of neutralization in such cases not exhibiting absolute constancy, and the dissociation of the dissociated salts being incomplete. This simple principle does away with the cumbrous hypothesis that each acid and base possesses a certain "avidity" or "affinity" peculiar to itself—an hypothesis which is, as I then pointed out, at variance with many facts of the case. A very striking confirmation of my views has been afforded by finding that the heat of neutralization of sulphuric acid in very weak solution is normal, thus verifying a prediction which I made on the strength of the above considerations.

I formerly held that the dissociation which explains endothermic reactions cannot be that of the product, but only that of the reagents; this I still think is true in cases where the product would dissociate into the same substances as the reagent would (if this latter could dissociate)—*e.g.* the hydrate of a salt dissociating into water and the elements composing the salt—but it is not true in other cases; for instance, a hydrate formed by dissolving a salt may dissociate into acid and base, and cause thereby an absorption of heat.

As with two possible reactions, where the products remain within the sphere of action, that which develops the most heat will occur to the exclusion of the other, so in two possible decompositions where the products remain within the sphere of action, that which absorbs least heat will occur to the exclusion of the other; and the question consequently arises, Why does a hydrated salt dissociate into acid and base, instead of into the anhydrous salt and water? The probable explanation is that in many cases the latter dissociation would be the more endothermic of the two; for the salt molecules in various contiguous hydrates are so far removed from the sphere of each other's attraction, that their attraction for each other would be practically *nil*, and the hydrate could only dissociate to form water and *free* salt molecules, absorbing in so doing a quantity of heat exceeding the observed heat of dissolution by an amount corresponding to the heat of fusion and volatilization of the salt, and exceeding in many cases the heat of neutralization itself. The presence of excess of water would moreover practically prevent the dissociation of the hydrate into water and the anhydrous salt.

A class of endothermic changes which present considerable difficulties are those which occur without the absorption of external energy in living organisms. We are at present so utterly ignorant of the nature of the reagents and products that it is hopeless to attempt any explanation of the *modus operandi* in these cases, but a suggestion made by Mr. Warrington at the recent meeting of the British Association with regard to the nitrifying organisms indicates the direction in which such an explanation may be obtained on the same principles as those given in the cases here discussed. SPENCER U. PICKERING.

THE WORKING OF THE TECHNICAL INSTRUCTION ACT AND THE LOCAL TAXATION ACT.[1]

THE Secretaries of the National Association for the Promotion of Technical and Secondary Education, in reporting on the working of the Technical Instruction Act, have to congratulate the Association on the rapid progress which has been made during the last year in taking advantage of the benefits of the Act. This is partly to be ascribed to the grant of a small sum by the Science and Art Department to meet local effort, but chiefly to the allocation to County Councils of England and Wales, under the Local Taxation Act of this year, of a sum amounting in all to £743,000, with permission to use it for the benefit of education over and above any sum that may be raised by rate under the Technical Instruction Act.

Technical Instruction Act, 1889.—The number of local authorities in England and Wales which have taken advantage of the Technical Instruction Act has risen from *four* to *forty* since the date of the Manchester Conference a year ago. These districts are as follows:—Atherton, Aberystwith, Barnsley, Birmingham, Birkenhead, Blackburn, Burnley, Burslem, Bridgwater, Bingley, Bolton, Blaenau Festiniog, Cardiff, Coventry, Darwen, Guiseley, Keighley, Kidderminster, Manchester, Maidstone, New Mills, Macclesfield, Northampton, Nottingham, Oxford, Rochdale, Rotherham, Sheffield, Stockport, Salford, Shipley, Sherborne, Southport, Stalybridge, Worcester, Wakefield, Wrexham, Westmoreland, Widnes, and York. This list is probably not complete. In addition to the above, several of the Welsh County Councils have appointed their Intermediate Education Joint Committees to be Committees under the Technical Instruction Act.

Local Taxation Act, 1890.—In addition to these districts, a number of counties have taken action in the direction of utilizing the local taxation grant under the machinery of the Technical Instruction Act.

The following English counties have already resolved to set aside the whole or part of the money for education:—

Shropshire has set aside the whole of its share, amounting to £6543, for education, and the Technical Instruction Committee has presented a valuable report on the use of the money.

Somersetshire has set aside the whole of its share, about £11,000, for education, and is now engaged in considering applications.

The Technical Instruction Committee of Hertfordshire has recommended that the whole of the sum (£6429) be devoted to education.

Staffordshire has voted £7000 for education, and a scheme for its distribution is being framed.

Oxfordshire has set aside half of the grant, about £2000, for education, and Gloucestershire has also voted half the grant for the same purpose.

The North Riding of Yorkshire has voted £2000 for education.

Cheshire and Devonshire have determined to devote some part of the fund to education.

Leicestershire gives £300 to the Leicestershire Dairy Association, and Westmoreland gives £250 to existing schools, to be spent on apparatus.

The county borough of Croydon has voted the new fund to meet capital expenditure on technical instruction.

Besides these twelve districts (eleven counties and one county borough) which have definitely voted the whole or part of the new fund for education, the subject is now receiving careful consideration in a large number of districts, in many of which the new fund is practically certain to be applied, at least in part, to educational purposes.

Conspicuous among these districts is the county of Lancashire, which was the first to move in the matter, having appointed a Technical Instruction Committee in August last, which is just now reporting results of exhaustive inquiries as to the best means of assisting education from the new fund. Essex also has advertised for applications for a share of the money, and is now considering such applications with a view to assisting technical education. Committees have been appointed to consider the question in the following twenty counties:—Kent, Wiltshire, Cornwall, Berkshire, Northumberland, Peterborough, Southampton, Cumberland, Durham, East and West Sussex, Cambridgeshire, Worcestershire, Warwickshire, Dorset, West Riding, East Riding, Bedfordshire, and Herefordshire, and London. In London, however, the bulk of the grant for the present year has been used for the reduction of rates.

A large number of county boroughs are considering the desirability of using the new money for education. It is stated to be most probable that it will be so used in Nottingham, Salford, Blackburn, and Bradford. Worcester proposes to increase its grant under the Technical Instruction Act by £450, to be taken out of the new fund.

In addition to the above, the following county boroughs

[1] Secretaries' Report, read at the Conference on December 5.

among others, have the matter now under the consideration of a committee :—Barrow, Bootle, Burnley, Canterbury, Gateshead, Hull, Leeds, Norwich, Oxford, Southampton, and Wigan.

In Wales the County Councils, with at most one or two exceptions, are proposing to utilize all the new fund for the purposes of education. In most cases the money will be used under the Intermediate Education Act, but some Councils, as, for example, Cardiff, have resolved to divide the fund between intermediate and technical education.

The general results hitherto attained, so far as the information of the Association goes, which is probably incomplete, may be summarized as follows :—

English.

County Councils which have voted money to education under the new Act	11
County Councils which have appointed committees to consider the question	22
Total counties moving in the matter ...	33 out of 49

This result has been attained during the short period of four months since the passing of the new Act, during the first half of which time hardly any County Councils were sitting. The figures for county boroughs are as follows :—

English county boroughs working the Technical Instruction Act	17
County boroughs allotting the new fund for education, but not rating themselves ...	1
Other county boroughs considering the application of the new fund for education ...	9
Total county boroughs moving in the matter	27 out of 59
Other districts in England working the Technical Instruction Act	19

The general result gives a total of 47 local authorities as yet assisting technical education in England.

This is exclusive of the Welsh counties and county boroughs, which, broadly speaking, may be said to be devoting almost the whole of the new fund to the purposes of education.

The total number is likely to be very largely increased when it becomes generally known that there is every reason to believe that the grant, or at least so much as is applied to education, will be renewed in the future.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, December 8.—M. Duchartre in the chair.—Observations of minor planets made with the great meridian instrument of Paris Observatory, from Oct. 1, 1889, to March 31, 1890, communicated by Admiral Mouchez.—Experiments on the mechanical actions exercised on rocks by gases at high pressures and in very rapid movement, by M Daubrée. The author applies the results recently arrived at (*Comptes rendus*, December 1) to the creation of volcanic ducts, and shows that it is probable that they are produced by mechanical actions much superior to the volcanic actions of which eruptions are the effects.—On the membrane of the lymphatic sac of the œsophagus of the frog, by M. Ranvier.—Proof that π cannot be the root of an algebraic equation having entire coefficients, by Prof. Sylvester. It is remarked that this proof should be substituted for the note by the same author, which unfortunately appeared in *Comptes rendus* of November 24. The latter note, which only dealt with a restricted case of the theorem enunciated in the text, is affected by inaccuracies which render it of no value.—A new method of studying the compressibility and the expansion of liquids and gases; results obtained with oxygen, hydrogen, nitrogen, and air, by M. E. H. Amagat. The experiments have been made between 0° and 200° C., and with pressures from 100 to 1000 atmospheres. The results obtained indicate that the coefficient of expansion of hydrogen at constant pressure diminishes regularly with increase of pressure. In the cases of oxygen, nitrogen, and air, the coefficient is at a maximum at the commencement, and this maximum corresponds to the pressure at which the product pv has the least value. The results obtained when the gases were reduced to constant volume show that $\frac{dp}{dt}$ is always greater between 0° and 100° than between 100° and 200°. The coefficients between 0° and 100°, at a pressure of 500 atmospheres, are 3·698, 3·085, 2·971, and 1·895, for oxygen, air, nitrogen, and hydrogen respectively. The values obtained at other pressures and temperatures follow a similar sequence.—Observations of Zona's comet, made with the great equatorial of Bordeaux Observatory, by MM. L. Picart and Courty. Observations for position were made on November 29 and 30.—On the observations of the transits of satellites of Jupiter and on the occultations of stars, by M. Ch. André.—On a transformation of motion, by M. Dautheville.—On the fluoride of allyl, by M. H. Meslans. Some of the physical and chemical properties of this compound are given. This ester is a colourless gas, possessing an alliaceous odour; it is formed from the iodide according to the equation $C_3H_5I + AgF = C_3H_5F + AgI$.—On some endothermic and exothermic reactions of organic alkalies, by M. Albert Colson.—On some derivatives of dimethylaniline, by M. Charles Lauth. A method of preparing tetramethylbenzidine is given, by which a yield of 40 per cent. may be obtained. Tetramethylbenzidine in hydrochloric acid solution is acted on at 45° by ferric chloride; fine green crystals of an unstable dye are produced, of which the formula is shown by analysis to be $C_{16}H_{21}ClN_2O$.—Contributions to the study of the nucleus of Spongidæ, by M. Joannes Chatin.—On the new class of jumping Acarina (*Nanorchestes amphibius*) from the coast of the British Channel, by M. Topsent and Dr. Trouessart.—On the age of sands and clays of the south-east, by MM. Ch. Depéret and V. Leenhardt.—Observations on extracts of meat, by M. Balland.

THE SYSTEM OF THE STARS.

The System of the Stars. By Agnes M. Clerke. (London: Longmans, Green, and Co., 1890.)

THE gifted author of this work became justly famous by the publication of her now classical "History of Astronomy during the Nineteenth Century." The mass of accurate information there brought together, and the delightful way in which it was related, won well-earned praise on every hand. Her success in that effort has now encouraged her to a more ambitious one. In addition to the simple relation of facts, she ventures to give her opinions on the various inferences which have been drawn from them by those who have spent many years in elaborate investigations. Still, "the statement of facts has been kept primarily in view, but the more important efforts to interpret them have been noticed, and the difficulties attending rival theories impartially pointed out."

We may look upon the book as consisting of two parts, one simply presenting a most valuable mass of information, while the other gives the author's views on contemporary work. As far as the first part is concerned, Miss Clerke has done her work admirably. We regret, however, for her own sake, that she has not confined herself entirely to this kind of work. A trustworthy book, bringing together all the latest discoveries and views of competent judges as to their true meaning would have been priceless, and no one has better opportunities for such an undertaking than Miss Clerke. As it is, we find a certain amount of information, selected rather than complete, intermingled with her own views. Certain facts have been omitted, not with the intention of misleading, but because their importance was apparently not recognized.

The first two chapters give general ideas of the problems of sidereal astronomy, and the methods of research which are adopted. The third chapter deals with "Sirian and Solar Stars," and here we get the first glimmerings of the author's special leaning to what may be called the "electrical theory." There is little difficulty connected with these groups of stars: it is generally agreed that the Sirian are the hottest, and that they have a definite evolutionary connection with the solar ones. Like Vogel, the author includes amongst the Sirian stars those stars of Orion (*e.g.* Rigel) which are characterized by very few visual and comparatively few photographic lines. Although their spectra show hydrogen absorption conspicuously, they differ very widely from the Sirian stars in other particulars. Their structure is not improbably of a very different character, due no doubt to their connection with the great nebula. Condensations taking place away from such a widely-diffused nebulosity probably follow a different path, and for the present the Orion stars should be classed apart from the more perfectly formed ones of the Sirian type. α Cygni, again, is included amongst the "solar stars," although its spectrum exhibits very wide divergences from that of the sun; the characteristic structure about the G region is entirely absent, while there are many well-marked non-solar lines in its spectrum. Altair, also, is said to be located between the Sirian and solar stars; but here again there is little resemblance to either, beyond the lines of hydrogen; the diagram on p. 43 makes this sufficiently evident. The more the "solar stars" are studied, the more it seems probable, as Mr. Lockyer has pointed out, that they must be divided into two groups—one of increasing temperature, including such stars as Aldebaran, α Cygni, and Altair; the other of decreasing temperature, including such stars as Procyon, Capella, Arcturus, and the sun.

The author advocates that the difference between the Sirian and solar stars can be accounted for by assuming the solar stars to be the more strongly electrified. It is argued that an increase of temperature in such a star as the sun would increase rather than diminish the complexity of its spectrum, by increasing the absorbing metallic vapours. It is not evident, however, how a diminution of the electrical repulsion would cause such an increase of the hydrogen absorption as that indicated in the spectra of the Sirian stars, the author simply asserting that the layers of hydrogen would be much more concentrated than at present. The increased thickness of the hydrogen lines is more probably due to some cause which increases the quantity of hydrogen in the atmospheres, and for the present, at all events, that may be regarded as the dissociation of the metallic vapours due to the increased temperature brought about by condensation.

Chapter iv. deals with the stars having banded spectra. These, it is well known, are of two types—one showing dark flutings most probably of metallic vapours, and the other dark flutings of carbon. They form Secchi's third and fourth types respectively. Flutings undoubtedly indicate that the vapours producing them are at a comparatively low temperature, and the presumption would be that the red stars are cooler than the yellow and white ones. On this point it is remarked that "the alteration obviously implies an augmented extent of absorbing atmosphere. For the bands must originate in a region of less heat—that is, at a greater distance from the stellar photospheres than the lines."

Let us consider first of all the stars of the third type, in which the hottest members show a fluted spectrum superposed upon a line spectrum, whilst there are practically no indications of the hydrogen lines. It has been suggested on various grounds that the stars of this type are not stars in the true sense of the word, but that they are of a cometary nature; that is, that they are composed of discrete masses, and not of a photosphere surrounded by glowing vapours. Perhaps the chief evidence in favour of this view lies in the alleged existence, in the spectra of these stars, of the bright carbon flutings which characterize the spectra of comets. The author does not consider the evidence on this point conclusive, but this appears to be partly due to the fact that all the evidence has not been brought together. In Nova Orionis, with a well-marked spectrum of this type, Dr. Copeland demonstrated the presence of two of the cometary flutings with almost absolute certainty (*Monthly Notices R.A.S.*, vol. xlvi. p. 110); Messrs. Lockyer and Fowler showed them to be present in α Herculis and Mira Ceti (Proc. Roy. Soc., vol. xlvii. p. 35); and, more recently, Mr. Maunder has stated that in the spectrum of α Herculis the brightest green fluting is coincident in position with the chief hydrocarbon band, and, moreover, presents exactly the same appearance ("Greenwich Spectroscopic Observations," 1888, p. 13). The brightening of this same fluting at the maximum of Mira tends to the same conclusion. Not a single one of these important observations, however, is referred to by Miss Clerke, although, if they are confirmed by future work, they must inevitably revolutionize the old idea that the red stars of the third type are "suns." The objection that the dark band adjacent to this, if an effect of contrast, would indicate that in the stars where it appears very dark there was no continuous spectrum at all does not hold good. A sun-spot appears intensely dark by contrast with the surrounding photosphere, and yet we know that it is brighter than the electric light. It is further objected that the other two cometary bands do not present themselves; but the blue band was included in both Copeland's and Fowler's observations, and it must be remembered that the citron band is the faintest in comets, and that in the stars in question it may be masked by the dark flutings which fall near it. It is stated (p. 56) that "there are grave objections to admitting the reality of the masking," but, as these are not formulated, it is impossible to discuss them. Whether the masking be admitted or not, the third band seen in comets often assumes the positions of two of the apparent bright bands in the spectra of stars of the third type, and with the additional evidence of the other two flutings, it is only reasonable to suppose that comets and these stars are bound together by close ties of relationship. Hence we cannot agree that "conclusive evidence seems to be provided that stellar spectra of the third type originate at various heat-levels in powerfully ignited vaporous envelopes." The mere existence of a continuous spectrum cannot be regarded as evidence of the existence of a photosphere. Comets, as a rule, give continuous spectra in addition to their fluted radiation, but few would venture to assert that this is produced by the radiation of a photosphere. The case of Mira at maximum, when the hydrogen lines appear bright, is quoted as evidence of an intensely high temperature close to the supposed photosphere; but this, it should be added, is abnormal, and only occurs when, through some cause or other, the star is some hundreds of times its normal brightness.

In support of the view that the various phenomena presented by stars of this type are produced by a photosphere underlying a highly distended atmosphere, the observations of the intermittently hazy aspect of some of them is referred to. It is only necessary to add here a remark omitted by the author—namely, that this equally supports the "cometary theory" of their structure, and is, in fact, one of its essential points. The electrical theory is again brought to the front in connection with these stars, it being suggested (p. 61) that the red stars are more strongly excited than the Sirian and solar stars, and that, in consequence, the atmospheres are very widely distended.

Coming now to the other type of red stars, in which we get the cometary spectrum reversed, Miss Clerke is again in error. It has hitherto been pretty generally accepted that these stars are almost on the verge of extinction, but our author says that "their powerful incandescence is undoubted" (p. 64). The evidence of such a temperature depends upon very doubtful facts. In addition to the chief bands of carbon, the spectra exhibit six secondary bands, two of which agree almost in position with the D lines of sodium and the E line of iron, and on the strength of this it is stated that, "through the obscurity of the carbon bands can be distinctly seen a 'Fraunhofer spectrum'—a spectrum, that is to say, composed, like that of the sun, of dark metallic lines thrown out upon a continuous background. Among the substances originating in them, sodium is certainly, iron probably, recognizable." If the existence of the Fraunhofer lines be admitted, there should be no hesitation in connecting these stars with the solar stars, for a slight but certain carbon absorption is exhibited by the sun, and there would be no need for the subsequent remark (p. 89) that "their spectroscopic isolation leaves us without the means of tracing their relationships." It is more likely that the secondary bands are identical with those in the solar spectrum which are produced by the absorption of our own atmosphere (see Proc. Roy. Soc., vol. xliv. p. 92), and the approach to a planetary condition is thus plainly foreshadowed. This piece of important evidence is not referred to by Miss Clerke, notwithstanding its suggestiveness.

"Gaseous Stars and Nebulæ" form the subject of chapter v., the idea being to continue the succession from Sirian and solar stars, through the red stars and bright-line stars to nebulæ. If the stars of the fourth type and those like Rigel be omitted, this may be taken as the probable sequence of events. The nebulæ are closely connected with the bright-line stars, these, again, with the stars of the third type—the bright hydrogen lines here showing similarity of constitution; stars of the third type merge insensibly into stars like Aldebaran and α Cygni, and, finally, into stars like Sirius.

So far so good; but the author is inconsistent. The Orion stars had previously been grouped with those of the first type, but on p. 72 we find it stated that "the brilliant stars of Orion may be said to mark the first stage on the road to nebulosity." We first find nebulæ placed at one end of the series and then at the other.

Opinions are still divided as to the interpretation of the spectra of "gaseous stars," but these bodies can certainly no longer be regarded as suns; they are similar in structure to the nebulæ, whatever that may be. There are some nebulæ which appear as little more than points of light, and we have Prof. Pickering's word that their photographic spectra strongly resemble those of the bright-line stars. Visually, their spectra are identical with those of such widely-diffused masses as the Great Nebula in Orion. A more perfect sequence of spectra from nebulæ to stars like Sirius could not be wished for.

"Sidereal Evolution" forms the subject of chapter vi. Nebulæ were formerly regarded as quite "distinct and of another order from the group of cosmical bodies to which our sun and the fixed stars belong"; but now we can agree with Miss Clerke in accepting the view that they gradually "merge into unmistakable suns" (p. 84).

"But when we come to the various classes of stars, the order of their succession is less easily determined. The earliest and most obvious idea on the subject was based on a false analogy between the colours of the stars and the colours of glowing terrestrial solids. Red stars, it was thought, should be regarded, because they had cooled from a condition of white heat, as older than white stars. The colours of stars, however, depend primarily upon the quality and extent of their absorbing atmospheres, and quite secondarily upon their stage of incandescence" (p. 85).

Surely the quality of the absorbing atmosphere must also depend upon the stage of incandescence, and colour may therefore still serve as a guide to the temperature and age of the stars. That the red stars of the third type are young may readily be granted from the evidence previously referred to; but, at the same time, it must be allowed that their temperature is comparatively low. It is, however, argued that the stars of the fourth type are also at an early stage of growth, but the evidence depending upon their alleged intermittently hazy aspect, indicating enormous atmospheres, is not conclusive on this point. In fact, the authorities quoted (Messrs. Pogson and Peek) have only observed it in *variable* stars of the *third* type. From the fact that there is carbon absorption in the sun, it seems reasonable to suppose that the fourth type stars are at a lower temperature than stars like the sun, and are probably the result of the cooling of such bodies.

The discussion of the sun's status amongst celestial bodies naturally comes here. That it was once a star like Betelgeuse, then like Aldebaran, is granted. But has it passed through the Sirian stage? This involves the question of whether the "solar stars" are divisible into two distinct groups, but our author is not quite clear upon this point. She remarks that "it is scarcely conceivable that a state abolished as an effect of condensation should be restored by its further progress" (p. 91). If there are two groups of "solar stars," one group will include bodies a little more condensed than the stars of the third type, in which perfect photospheres have not been formed, while the other will include bodies formed by the further condensation of such stars as Sirius. The two states would not be identical. We know that the sun has a photosphere, and hence the suggestion that it is a cooling body. Its relation to the stars of the fourth type strengthens the view that the sun has already passed through the Sirian stage and will eventually be a fourth type star. Miss Clerke, however, does not accept this view of the effects of further condensation upon a Sirian star, but suggests another which has not a single fact to support it. It is pointed out that the spectrum of the satellite of Sirius, if it could be observed, might give some clue to the spectrum of a waning body; and she is bold enough to predict that it will prove to be of "an undistinguished character, interrupted neither by bands nor conspicuous dark lines, and feeble, not through effects of absorption, but intrinsically. The same dull uniformity may be expected to belong to the spectra of all stars of impaired splendour" (p. 92). What, then, will be the transition stage, say between Sirius and such a body as that suggested? The broad hydrogen lines could not disappear suddenly, and we know that there are no stars showing fine hydrogen lines alone. In fact, it is especially emphasised (p. 42) that "the conspicuousness of rays due to absorption by ordinary metals in the spectra of white stars varies inversely with that of the hydrogen series." Some solar stars, at least, must therefore represent the stage that will be arrived at by the cooling of such a star as Sirius, and the evidence tends to show that the sun is one of them.

Further, if the spectrum of such a waning star were simply dimly continuous, the absence of an atmosphere would be indicated. We certainly know that the moon has no atmosphere, but it does not shine by light of its own. Even the earth has sufficient atmosphere to give a very definite spectrum of absorption, and this atmospheric absorption must have been much greater when the earth was hotter than at present. Cooling stars are not likely, therefore, to give such spectra as Miss Clerke supposes, for we know that a powerfully absorbing atmosphere remains after the photospheric luminosity has disappeared. The spectrum of such a cool atmosphere would no doubt be a fluted one.

Temporary and variable stars occupy the next two chapters, and some valuable information is brought together in an interesting way. Among the spectroscopic observations of new stars, probably the most important were those of Nova Cygni. The most striking thing here was the increased brilliancy of the chief nebula line as the star faded away. That is to say, as the star cooled, it became a nebula, thus affording very decided evidence that nebulæ are comparatively cool. The dimming of new stars takes place so suddenly that it is certain only small bodies can be in question, and the suggestion has been made that new stars were produced by collisions of meteor-swarms. For collisions of this kind, Miss Clerke substitutes "grazing encounters with nebulous masses revolving in hyperbolic orbits, and overthrowing, by their proximity to the attractive body, a thermal equilibrium already eminently unstable." In the case of Nova Cygni no star had previously been recorded in its place, and it is difficult to conceive that such a grazing of a dark body, supposing one existed, with a moving nebulous mass could produce such a brief "conflagration" as was observed.

The old theories of stellar variation, assuming the existence of immense masses of slags in the photospheres, or that one side of a variable star was brighter than the other, have long been discarded. No single explanation is good for all variables, but there is no difficulty with those of the Algol type. After brief references to the explanations which have been suggested for the red stars, Miss Clerke concludes that "the time has not come to formulate a theory of stellar variability" (p. 125). The only comprehensive one we have as yet—the collision theory—is not considered sufficient by Miss Clerke; but careful consideration will remove the objections made against it. This theory assumes as proved the cometary character of stars of the third type, and suggests that the increase of light at the maximum of a variable of this kind is produced by the collisions at the periastron passage of satellite comets or swarms of meteorites. It is objected (p. 124) that this state of things could not long subsist, as the satellite swarm must inevitably become extended into a ring, with complete effacement of variability. This is certainly true, but we have only to look at the "November swarm" in our own system to understand that the disruption of the satellite comet need not be very speedy. This swarm has been observed now for at least a thousand years, and yet the brilliancy of the showers is apparently not diminished. Mira Ceti is the only variable of this class which has been observed for a long period, and the observations in this case only extend over three hundred years. On p. 124 we read further:—

"The periodicity of variable stars is, besides, of far too disturbed a kind to be thus accounted for. Systematic stability would assuredly prove incompatible with the enormous irregularities it discloses. The abrupt acceleration or retardation, for example, by a month of the hypothetical attendant swarm of Mira, would be impossible without such a total change in the elements of its circulation as would unmistakably break the continuity of its returns. But there are other objects far more recalcitrant than Mira to this mode of explanation. Take the outbursts of U Geminorum. They are not wholly capricious. There is a certain disorderly order about them by which they are manifestly akin to the changes of the more strictly periodical stars. We cannot relegate them to a class apart and invent a fresh hypothesis to suit them; the collision theory, to be acceptable in the one case, must be capable of meeting the other. But we can scarcely conceive any construction of assumptions by which such an extension of its powers could be effected."

Irregularities such as are here referred to are almost bound to occur if the collision theory be true. A star is not limited to one short-period comet any more than is our sun. There may very well be swarms of various masses travelling round the star in regular orbits, and occasionally a swarm travelling in an open orbit may enter the system. These swarms would so react upon each other and upon the central swarm that irregularities would be the inevitable result. Again, the central swarm might vary locally, like the Andromeda nebula, so that the revolving swarm would not always encounter it under exactly the same conditions. That the intervals between successive maxima and the magnitudes at maxima are not constant does not prove that the actions are not periodic.

In NATURE, vol. xlii. p. 550, there are some interesting examples of the apparently irregular results which might be produced by the integration of two sources of regular light variation. Two or more swarms of regular periods with the occasional advent of one moving in a parabolic or hyperbolic orbit, can be made to explain all the facts relating to this class of variables. In the variables of the fourth type, the same explanation holds good, if we consider the direct luminosity of the cometary swarms to be added to that of a dim condensed central body. Miss Clerke, however, supposes that variability depends upon extensive atmospheres, these being disturbed periodically in some way or other, probably by the tidal action of a satellite, so as to produce the observed fluctuations of light. It is a question whether such an atmospheric disturbance could increase the apparent brightness of a star hundreds of times.

The succeeding eight chapters are mainly descriptive, dealing with colour phenomena, double stars, stellar orbits, star-clusters, and the forms of nebulæ. It is only necessary to say of these that they are admirable.

Chapter xix., "The Nature and Changes of Nebulæ," discusses the relations of nebulæ and comets, and nebular variability. Referring to comets and nebulæ, it is stated (p. 286) that "traces of a spectroscopic analogy can indeed be shown to exist; but they are met with only in the secondary elements of each spectrum. The resemblance seems only incidental; the dissimilarity essential." It has, however, previously been pointed out (p. 76) that two faint comets observed by Dr. Huggins in 1866–67, gave spectra identical with that of a faint planetary nebula. This may well be regarded as conclusive spectroscopic evidence of the similarity between comets and nebulæ, but although it is apparently only regarded as of secondary importance, "it does not detract from the closeness of a physical analogy." It seems unphilosophical to rely on telescopic similarity when such conclusive spectroscopic evidence is at hand. We might go further than Miss Clerke, and say that as a comet is usually regarded as a swarm of meteorites the same view must be accepted for nebulæ. The information relating to the views on the temperature of nebulæ is very meagre. Some argue that they are intensely hot, whilst others argue that they are cool bodies not unlike comets. Apparently the only statement on this important subject is that on p. 77, where it is stated they "are not greatly heated." Indeed, the evidence afforded by their cometary relationships and by Nova Cygni is conclusive. Yet, as late as 1889, Dr. Huggins stated his belief that the temperature of nebulæ is very high.

It will thus be seen that, although a good deal of Mr. Lockyer's recent important work is left out of consideration, two of his main propositions are accepted by Miss Clerke; viz. (1) "nebulæ merge into unmistakable suns," and (2) they "are not greatly heated."

The remaining chapters consider the distances of the stars, the motion of the solar system, proper motions, the Milky Way, the "status of the nebulæ," and finally the "construction of the heavens." The two latter really discuss the distribution of stars and nebulæ, and bring together a wonderful amount of information which has hitherto been much dispersed.

In justice to Miss Clerke, it is only fair to add that she has exercised a sound judgment on many problems, and has made many valuable suggestions as to the lines on which future investigations should be proceeded with.

The book is well illustrated throughout, among the illustrations being reproductions of some of Mr. Roberts's marvellous photographs. With the exception of that of the Andromeda nebula, these are highly satisfactory.

In conclusion, we would again express our unqualified admiration of a good deal that the book contains, but we cannot help feeling that its value as a contribution to astronomical literature would have been greater if the author had confined herself to simply giving a trustworthy account of contemporary astronomical researches, and of the views held by competent thinkers. A safe and impartial guide to current thought is still a desideratum.

F.

ACROSS GREENLAND.

The First Crossing of Greenland. By Fridtjof Nansen. Translated from the Norwegian by Hubert M. Gepp. With Maps and numerous Illustrations. Two Vols. (London: Longmans, Green, and Co., 1890.)

THE only serious fault to be found with this book is that it is much too long. Only a small proportion of it is devoted to the actual crossing of Greenland, the rest being occupied with matters which might have been, and ought to have been, dealt with concisely. So far as it relates directly to the author's experience, the work is one of the deepest interest. Dr. Nansen is not only an explorer of remarkable courage, resource, and foresight; he has also many of the qualities of a man of letters. He knows exactly on what parts of his story emphasis should be laid, and his skill as a writer is so great that even incidents which do not in themselves seem to be either very striking or very suggestive are made to add to the freshness and vividness of his tale. One of the chief elements of attraction in the book is the more or less unconscious revelation which the author gives of his own character. He has evidently an intense delight in adventure for its own sake, and he writes in such good spirits, with so unaffected a delight in the remembrance of all the difficulties he has overcome, that it is impossible not to follow his record with sympathy and admiration; and every reader will lay down the work with a feeling of sincere regard for a traveller who is at once so hardy, enterprising, and enthusiastic. He has been most fortunate in his translator, who has done his work so well that the narrative reads almost as if it had been originally written in English. The maps and illustrations, too, are unusually good.

In the summer of 1882, when still a very young man, Dr. Nansen spent some months in the northern seas on board the *Viking*, a Norwegian sealer. The ship was caught in the ice off the eastern coast of Greenland, and it was at this time that he first felt a strong desire to investigate the strange, desolate region at which, many times a day, he gazed from the maintop. In the following year the wish was renewed and strengthened when he read of Baron Nordenskiöld's return from the interior of Greenland; but many things came in the way to prevent the fulfilment of his scheme. In 1887 he attempted, through the Norwegian University, to obtain from the Government the means of organizing an expedition; but the Government declined to support the proposal, and one of the newspapers expressed the opinion that "there could be no conceivable reason why the Norwegian people should pay so large a sum as 5000 kr. in order to give a private individual a holiday trip." Herr Augustin Gamél, however, who was already known as an enlightened and generous promoter of Arctic research, offered to provide the necessary funds; and thus Dr. Nansen was enabled at once to make preparations for his contemplated journey. Three of his countrymen—Otto Sverdrup, Oluf Christian Dietrichsen, and Kristian Kristiansen Trana, all of whom were admirably fitted for the work—undertook to accompany him; and he also secured the services of two Lapps—Samuel Johannsen Balto and Ole Nielsen Ravna. The Lapps were of less use than might have been expected; and under a less genial leader they might have become extremely troublesome. Dr. Nansen knew how to appeal to them, and nothing in its way could be better than his description of the devices by which he contrived to inspire them with a little of his own energetic spirit. It may be noted to his credit that he has nothing to say of any of his companions that may not be read with pleasure. He acknowledges frankly and gratefully all that he owed to them in carrying out his bold and hazardous project.

On May 2 the party left Christiania for Leith, whence they started for Iceland; and about a month afterwards they joined the sealer *Jason* at Isafjord, with the owners of which he had come to an agreement that the captain should do his best to put them ashore on the east coast of Greenland. Dr. Nansen has much to say about the voyage to Iceland, about cruising in the ice, about the bladder-nose seal and its capture, and about life on the *Jason*; and some of the facts he records are not without interest. But they are out of place in a work of this kind, which stands in no need of "padding." Even the account of "Ski" and "Skilöbning," by which the chapters on these subjects are preceded, might with advantage have been shortened. Here, however, the author has some excuse for the minuteness of his descriptions, for without "ski" the journey could scarcely have been undertaken, and the subject is one of which he is able to write picturesquely and effectively.

They quitted the *Jason* on July 17, hoping that they might effect a landing without much delay. But for many days they drifted southwards, and sometimes, battling for life among the floes, they could not but feel that success was almost impossible. Dr. Nansen never lost heart, and no part of his story is more stirring than that in which he records the unexpected and perilous adventures encountered at this early stage of his journey. When at last they reached land, they were, he says, "just like children." "A bit of moss, a stalk of grass, to say nothing of a flower, drew out a whole rush of feelings. All was so fresh to us, and the transition was so sudden and complete. The Lapps ran straight up the mountain-side, and for a long while we saw nothing more of them." Dr. Nansen was so relieved and delighted that, when gnats settled on his hand, he "let them sit quietly biting, and took pleasure in their attack." On the same day they embarked again, and pushed on quickly, as it was necessary for them to start from a more northerly position. They landed at their last camping-place on the eastern coast on August 10, and on August 15, after various preliminary arrangements, they set off for the interior, intending that their goal should be Christianshaab. Afterwards Dr. Nansen found it expedient to alter the route, and to make for Godthaab.

Of the journey itself little need be said, as the main facts are already well known, and an adequate conception of the details can be obtained only from the author's fascinating narrative. For some time they had to mount steadily, until they reached a height of 8970 feet. Then they came to a comparatively flat region, beyond which the ice-sheet descended gradually towards the western coast. The difficulties were enormous, for they had to drag their provisions on sledges, and they were repeatedly caught in violent storms, during which they were obliged to remain for shelter in their small tent. The cold was sometimes terrible; their rations were anything but abundant; and they had to sleep in bags. But no obstacles were formidable enough to daunt the leader of the party, and his task was lightened by the fact that he succeeded in maintaining from first to last the most friendly relations with his comrades. Although few incidents of any importance broke the monotony of their progress, Dr. Nansen found much to interest him in such scientific observations as the conditions rendered possible; and even in the interior of Greenland elements of splendour and beauty were not wanting. The greater part of their travelling was done in the daytime, but at first they thought it best to proceed by night. Here are some of Dr. Nansen's reminiscences of his impressions during their night-marches:—

"But if we often suffered a good deal in the way of work, we had full compensation during these nights in the wonderful features of the sky, for even this tract of the earth has its own beauty. When the ever-changing northern lights filled the heavens to the south with their fairy-like display—a display, perhaps, more brilliant in these regions than elsewhere—our toils and pains were, I think, for the most part, forgotten. Or when the moon rose and set off upon her silent journey through the fields of stars, her rays glittering on the crest of every ridge of ice, and bathing the whole of the dead frozen desert in a flood of silver light, the spirit of peace reigned supreme, and life itself became beauty. I am convinced that these night-marches of ours over the 'inland ice' left a deep and ineffaceable impression upon the minds of all who took part in them."

As they advanced over the ice-sheet, they longed more and more for land; and one afternoon, just two months after they had left the *Jason*, they were enchanted by the sudden appearance of a snow-bunting, from which they knew that the western coast could not be very far off. On September 19, Balto caught sight of a black spot in the distance, and immediately afterwards all of them were able to make out, through the mist of snow, "a long, dark mountain ridge, and to the south of it a smaller peak." On September 24, Dr. Nansen found himself "on the brow of an ice-slope which overlooked a beautiful mountain tarn, the surface of which was covered with a sheet of ice"; and shortly afterwards they had the pleasure of walking on solid ground. He says:—

"Words cannot describe what it was for us only to have the earth and stones again beneath our feet, or the thrill that went through us as we felt the elastic heather on which we trod, and smelt the fragrant scent of grass and moss. Behind us lay the 'inland ice,' its cold, grey slope sinking slowly towards the lake; before us lay the genial land. Away down the valley we could see headland beyond headland, covering and overlapping each other as far as the eye could reach."

On October 3, Dr. Nansen and Sverdrup reached Godthaab, where they were soon joined by their companions. For a moment it was unpleasant for them to find that they would have to spend the winter at this remote station; but they met with so much kindness that their stay proved to be in every way more agreeable than they anticipated.

Of the scientific results of the expedition, the most important is the establishment of the fact that the ice-sheet stretches in unbroken continuity over that part of Greenland which the party traversed. How far the ice-sheet extends towards the north we do not yet know; but Dr. Nansen concludes that "its limit must lie beyond the 75th parallel, for so far along the west coast it sends huge glacier-arms into the sea. Among these is Upernivik Glacier, in lat. 73° N., which has a rate of advance of no less than 99 feet in the twenty-four hours. So rapid a movement must presuppose the existence of an enormous interior ice-sheet, which can supply material for consumption on this huge scale." An idea of the form and elevation of the ice-sheet is conveyed by a section or profile drawing, constructed by Prof. Mohn and Dr. Nansen from numerous astronomical and barometrical observations, supplemented by the notes of Dr. Nansen's diary. This section shows that "the ice-sheet rises comparatively abruptly from the sea on both sides, but more especially on the east coast, while its central portion is tolerably flat. On the whole, the gradient decreases the further one gets into the interior, and the mass thus presents the form of a shield with a surface corrugated by gentle, almost imperceptible, undulations lying more or less north and south, and with its highest point not placed symmetrically, but very decidedly nearer the east coast than the west." Dr. Nansen indulges in some speculations as to the action of "great ice-sheets," but here his work is less satisfactory than in those passages in which he simply sets down what he himself has seen. Speaking of the fact that glaciers are stated by geologists to "have carried huge moraines of boulders and grit upon their backs," he says that to his mind "this idea is nothing less than absurd"; which is surely an odd way of talking about a conclusion based on a wide range of careful and exact observations. Dr. Nansen serves science more effectually in presenting facts as to temperature, snow- and rain-fall, and atmospheric pressure, and in describing the daily life of the Eskimo, some of whom he met on the eastern as well as on the western coast.

Dr. Nansen is now making preparations for a Polar expedition, which he proposes to undertake in 1892. If we may judge from his achievements in Greenland, he possesses in no common degree the special talents which are necessary for any measure of success in this larger and more difficult enterprise. No one who reads his book will hesitate to acknowledge that he has shown himself one of the ablest and most daring explorers of the present generation.

OUR BOOK SHELF.

Les Microbes de la Bouche. Par le Dr. Th. David. (Paris: Felix Alcan, 1890.)

THIS book will be found of considerable value. Although Dr. David does not record original observations of his own, most facts stated being copied from other works, he nevertheless deserves credit for putting together in concise form all that is known of the micro-organisms occurring in the oral cavity, on and in the organs of the mouth in health and disease. The morphology, cultural and physiological characters of most of these microbes are described in detail, including those of diphtheria, tubercle, and actinomycosis. From p. 205 to p. 262 the author gives a valuable account of the bacteria present in diseased teeth, but unfortunately he adds—probably for purposes of the professional dentist—a number of prescriptions on cosmetics, tooth powders, &c., which ought not to find a place in a scientific work of the character of the present book. The appendix on influenza might well have been omitted.

Notes on the Products of Western Afghanistan and North-Eastern Persia. By J. E. T. Aitchison, C.I.E., M.D., F.R.S. Pp. 228. (Edinburgh: Neill and Co., 1890.)

A REPRINT from the Transactions of the Botanical Society of Edinburgh, containing an alphabetical synopsis of the animal, vegetable, and mineral products of Western Afghanistan and Eastern Persia, together with their native names, with their English and Latin equivalents, and their applications. Dr. Aitchison's contributions to the botany and zoology of Afghanistan and the adjoining countries are well known to specialists, and the present work is an amplification of the economic branch of his investigations. Persia has been specially noted from time immemorial for its drugs, dyes, perfumes, and other vegetable productions, but much yet remains to be done in the elucidation of the plants which yield them. Dr. Aitchison was attached to the last military expedition to Afghanistan, and he was also naturalist to the "Delimitation Commission," and made very extensive collections of botanical and zoological objects, especially of the former. During the latter expedition he specially investigated the origin of the drugs, such as the asafœtida, obtained from umbelliferous plants, and the main results are given in a handsomely illustrated memoir that appeared in the Transactions of the Linnean Society.

The "Notes" now offered to the public afford another proof of the immense energy and perseverance of the author in collecting materials and information, often under great difficulties; and they will be welcomed by all interested in the subject. As the author informs us in some prefatory remarks, he has brought these notes together as a guide to future workers, having himself greatly felt the want of some such aid.

We believe that Dr. Aitchison contemplates another journey to Persia in order to extend his researches into the products of the country. W. B. H.

Metal-Turning. By a Foreman Pattern Maker. (London: Whittaker and Co., 1890.)

THIS book is written to explain and illustrate the practice of plain hand turning, and slide-rest turning as performed in engineers' workshops. The ornamental section of the craft is therefore entirely excluded. No attempt is made to describe all the numerous types of heavy lathes which are to be found in large workshops. The author tells us this in the preface, his object evidently being to treat the subject thoroughly from the works point of view, and not from that of the amateur manufacturer of ivory boxes and the like. The section on tools and tool angles is excellent, and will repay careful reading by turners; many, who are in all other respects good workmen, often make a fearful hash when grinding their tools.

When the much-abused "practical man" is induced to give his experience to the world in the form of a book, there is generally something worth reading and remembering to be found. This is the case in the work before us, which can be well recommended to all interested in its subject-matter. N. J. L.

The Century Arithmetic (complete.) (London: Blackie and Son, Limited, 1890.)

IN glancing through the pages of this volume, we are struck by the immense number of examples that are inserted; in fact, the work consists of practically nothing more than a series of exercises, commencing with simple addition and concluding with stocks. They have been arranged in an easy and progressive manner, and at the beginning of each new series of examples a typical case is worked out fully, and at the conclusion are mental tests which are given by inspectors. Intended as they are for Board schools and the like, the exercises should be found most instructive, for the subject can be grasped best by the constant working out of examples such as those that are here so copiously brought together.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Biological Terminology.

IN a recent number of NATURE (December 11, p. 141), Prof. T. J. Parker gives three suggestions in biological terminology, on which you will perhaps permit me to make one or two remarks, as his notes are *à propos* of some criticisms of mine on his paper on that subject (Proc. Austr. Assoc. Adv. Sc., vol. i., 1888).

(1) The term *agamobium* for the asexual generation in plants and animals, as suggested by Prof. Parker, certainly escapes the objection I raised to the term *blastobium*. I am not sure, however, that botanists, even though they might agree with Prof. Parker's general views on terminology, would be inclined to designate as an *agamobium* both the asexual state of a *Vaucheria* (for example) and the asexual generation of a fern. Prof. Bower in a recent paper (*Ann. Bot.*, vol. iv. No. 15) has drawn attention to the distinction made by Celakovsky between homologous and antithetic alternation of generations. The important differences between those two types of alternation would, I think, be in danger of being once more lost sight of if the asexual stages both of the homologous and of the antithetic type were known by the same name.

(2) My objection to Prof. Parker's use of the anglicized form of *ovarium* (ovary) would disappear, if "ovary," in its ordinary acceptation in botany, could be got rid of altogether, "ovule" of course following in its train. Megasporangium (for "ovule") is now generally in use, and it is possible that in time "ovary" may give place to some more suitable term, which will express the true morphological value of the structure known as the "ovary." For uniformity's sake one might wish to see either classical names or their English equivalents used throughout, and since we have already adopted *megasporangium*, *microsporangium*, *ovum*, *sperm* (or *spermatozoon*), &c., and may adopt *gamobium* and *agamobium* (for which there are no English equivalents), the balance seems to turn distinctly in favour of the classical as opposed to the English names.

(3) Prof. Parker advocates the use of special terms for certain "important stages in plant development." All botanists will, I think, accept—at least in time—the term *oosperm* in place of "oospore." That this term ought to be applied to the *unicellular* embryo only there can be no question. Prof. Parker objects to the use of *oosperm* (in Haddon's "Embryology") to indicate the advanced mammalian embryo. I unite with him in his protest, but might add that *oosperm* as applied to an advanced embryo is far preferable to the term *ovum* for the same structure (McKendrick, "Text-book of Physiology," vol. ii. p. 746). In Quain's "Anatomy," for instance, such phrases as "in an ovum of from five to six weeks" (vol. ii. p. 765, 9th ed.) are of frequent occurrence. Whether names *are* required for successive stages in plant development is perhaps an open question. At all events, I cannot see that Prof. Parker is justified in applying the term *polyplast* to the fully formed sporogonium of a moss. A body with the histological differentiation observable in the sporogonium of *Polytrichum* or even of *Jungermannia*, cannot surely be designated by the same term as that applied to the body to which Haeckel gave the name of *morula*. If "highly differentiated," surely it has ceased to be a *polyplast*. Personally, I would feel inclined to use the general term *embryo* for all stages of development after segmentation has begun.

R. J. HARVEY GIBSON.

Botanical Laboratory, University College, Liverpool.

Streamers of White Vapour.

I STAND this morning in my private room in the University building, looking out over the harbour, and away to the open expanse of Lake Ontario. The shore is to the south of me, and runs east and west. The wind is blowing from the north, and hence from the land over the water. The temperature of the air is about 3° or 4° F., and the temperature of the water is about 45° F.

The whole surface of the water, as far out as the eye can distinguish, is covered with a perfectly white mist like a low-lying fog, so that the appearance of steamers on the bay is that of vessels drifting through a cloud bank, but with the higher upper works and the smoke-stacks mostly elevated above the cloud.

The most peculiar phenomena, however, are the streamers of white vapour which rise in straight or spiral columns, very limited in breadth, but reaching to a great height. These may be seen by hundreds, some rising to a greater height, some to a less, although from the large extent of surface under view, the more prominent ones cannot be very near together. I have watched these streamers from year to year with great interest, for they always present themselves at the first appearance of very cold weather at the coming on of winter, and before the surface of such an immense body of water has had time to cool down after the summer heats.

You will see one of these streamers start up from its apparent bed of cloud, and, with a sort of wriggling, twisting motion, make its way upwards to a great height in a very few seconds, and drift slowly along with the wind, like a spindling but giant column of steam. They, in the meantime, undergo a slow but incessant change, and sometimes they gradually vanish at the top while being renewed from below, while at others they detach themselves at the base and float heavenward until they vanish in mid air or lose themselves in the overhanging and distant cloud.

The whole phenomenon reminds me very forcibly of the pictures of the solar streamers which are to be seen in various illustrated works on the sun, and the two are probably brought about by somewhat similar causes, although the difference in the degree of action must be almost infinite.

I have no means of determining the heights of these streamers except approximately. There is, however, a wooded island about one half a mile wide, and the distant shore of which is about five miles from the city. It is a common thing, under favourable circumstances, to see the streamers rise from the further side of that island to a height of from ten to twelve times the height of the tallest trees on the island, which would give a height of at least about 500 feet; and as the base of these streamers may be at some distance beyond the island, their height may occasionally be considerably above this estimate.

The continual shooting upwards of these, and their continual motion and change, offers a phenomenon at once very interesting and very beautiful. I have never seen the appearance at its best to last above five or six hours, and any second appearance is always inferior to the first. I may add that the same scene presents occasionally, in the spring, some of the finest mirages to be seen anywhere. N. F. Dupuis.

Queen's College, Kingston, Canada, December 2.

On the Affinities of Hesperornis.

Among some very useful and important papers recently issued by the Museum of Zoology of the University College, Dundee, appears one by Prof. D'Arcy Thompson, "On the Systematic Position of *Hesperornis*." In this excellent scientific brochure, Prof. Thompson has critically compared in detail the skeleton of a diver (*Colymbus septentrionalis*) with the skeleton of *Hesperornis*, as presented us by Marsh; and the outcome of this investigation has fully convinced the author of the work in question of the kinship, which undoubtedly exists, between the extinct *Hesperornis* and the existing pogopodine birds, as the divers, loons, and grebes. We have long been satisfied of these affinities, and firmly believed that the *Colymbidæ* were the descendants, perhaps direct descendants, of the toothed birds of the genus *Hesperornis*. It required but such comparison as has been so ably instituted by Prof. Thompson to make it quite clear to any thoughtful anatomist; and, as he hints, a similar comparison will probably go to show the fact that another extinct toothed bird-form, *Ichthyornis*, lies in the line of descent of the terns and their allies.

It is said by those who are opposed to these opinions that the agreement in skeletal characters between two such forms as *Hesperornis* and *Colymbus* are but superficial, and due to the fact that the birds did have in the case of the first, and now have in the case of the divers, similar habits.

The advocacy and adoption of such a view as this could but tend to mask their real affinities, impede the solution of the natural taxonomy of extinct avian forms, and be dangerous to the proper use of osteological characters in the premises. Hardly would "similarity of habits" produce morphological likenesses in such bones as the vomer, the pterygoids, the occipitals and the condyle they form, and a number of others which practically agree in *Hesperornis* and the *Colymbidæ*, and are very different in the *Ratitæ*.

So far as such a bone as the sternum is concerned, the fact whether it be "keeled" or "not keeled" must be used with no little caution when we come to decide upon the affinities of bird-forms, be they extinct or otherwise. And were the fossil remains of birds, which formerly existed upon the earth, in our possession in sufficient number and variety, I am quite sure that true avian kinships could not be established upon any such hard and fast lines as to whether or no their sterna were "carinated" or "non-carinated." We would undoubtedly meet with ostrich-types that could fly, and so have keeled sterna; and also ratite-types that enjoyed not such volant powers, and consequently possessed the "raft-sternum," as did *Hesperornis*, our great extinct ancient diver, which, as we know, was flightless, raft-sternumed, but withal, in the remainder of its skeleton, presenting all the fundamental characters of the now-existing Pygopodes, especially in so far as they are represented by the grebes and loons. R. W. Shufeldt.

Takoma, D.C., December 5.

A Swallow's Terrace.

In your issue of November 27, Mr. Warde Fowler gives a description of an unusually straggling nest of the swallow. An example to the contrary, of extreme neatness, which came under my notice a year or two ago, and which I still preserve, is the following:—My brother, on entering an old cottage in Somersetshire which had been empty for a long time, found in one of the rooms a lath, broken at one end, depending from the ceiling at an angle of about 30°. The lath was about 18 inches long, and on the free end was a swallow's nest containing four very handsome eggs, heavily marked with large blotches of purple-brown. The nest was perfectly circular and shallow, like a tea-saucer, its external dimensions being about 5 inches diameter by 2 inches deep. It was built of the usual materials, the exterior being of mud, with which it was secured to the lath, and the lining of hay with an inner lining of feathers. Close by were other swallows' nests, just inside the top of a chimney and quite open to the sky, so that a covered site does not seem indispensable if the nest be sufficiently sheltered. In view of this and the preceding description of nest with its fragile support, it would not appear surprising to hear of a swallow building on the branch of a tree provided it were in a well sheltered situation. Robert H. Read.

Cathcart, Glasgow, December 17.

Nests of the Red-backed Shrike.

Whilst writing on the subject of nests, I would like to remark that I examined three nests of the red-backed shrike this last summer, and that the colour of the linings appear to bear out the remarks of a correspondent which appeared in Nature some months ago. Two of the nests contained eggs of a pale pink ground-colour, whilst the eggs in the third were of a creamy-white ground-colour. In the third nest the lining was of roots, a few black horsehairs, red and white cowhair and a little wool. In the first two nests there was no white hair or wool, the lining consisting chiefly of roots and red cowhair. Although this seems to corroborate the experience of your correspondent, yet the difference in ground-colour of the three sets of eggs was so comparatively slight that I would not like to infer from these three nests alone that the colour of the nest-lining had any significance from a protective point of view.

Cathcart, Glasgow, December 17. Robert H. Read.

"Fire-ball" Meteor of December 14.

It will probably be of interest to many besides your two correspondents—whose letters are respectively dated from Sittingbourne in Kent, and Loughton in Essex—to learn that the remarkable meteor they describe was also observed about the time mentioned by them (9.45) in this neighbourhood.

Dr. Dixey, of Finchley, described it to me on the following day (Monday), remarking that "it would be sure to be in the papers"; and, moreover, the staircase of this house was brightly lit up, through the skylight above it, also at 9.45, I observing to my wife, who came to tell me of it, that the light probably came from a large meteor. My friend Dr. Dixey told me that he did not notice any trail. James Turle.

North Finchley, Middlesex, December 18.

THE FOSSIL MAMMALS OF NORTH AMERICA.[1]

THIS important contribution to our knowledge of the extinct mammals of the United States is the joint production of Profs. W. B. Scott and H. F. Osborn, of the Geological Museum at Princeton College, to whom we are already indebted for much valuable work on the subject. The present memoir is of more than ordinary importance, since the authors have endeavoured to complete our knowledge of forms already more or less fully described, rather than to add fresh burdens to the memory by recording a host of so-called new species and genera founded upon specimens which are not sufficiently characteristic to prove their distinctness from forms already described. Indeed, they have taken the opposite course, and endeavoured to show how the number of such species and genera may be reduced; not shrinking, as the manner of some is, from relegating when necessary some of the terms proposed by themselves to the rank of synonyms. This line of work, we are assured, is the one now urgently called for, as it is almost certain that the number of names which have been already proposed must, if properly defined and correlated, really include by far the greater proportion of the animals of the better known formations.

The work is divided into four parts; the first and second being by Prof. Scott, the third and fourth by Prof. Osborn. Part I. treats of the geological and faunal relationships of the Uinta beds; Part II. includes those mammals referable to the groups known as Creodonts, Rodents, and Artiodactyle Ungulates; Part III. is devoted to the Perissodactyle Ungulates; while the concluding Part is an endeavour to trace the gradual modification of the foot-structure of the Ungulates from the generalized older forms to the specialized types found at the present day.

In the first part we are told that in the Upper Green River valley in Colorado there are three well-marked groups of Tertiary strata overlying the Upper Cretaceous Laramie beds, and named, in ascending order, the Wasatch, Green River, and Bridger Eocene groups; the earliest Puerco Eocene being apparently missing between the Laramie and the Wasatch beds. The Bridger, or Middle Eocene, which is further divisible into three minor groups, is characterized as a whole by the presence of the now well-known Dinocerata, so fully described by Profs. Marsh and Cope. The geology of the Uinta beds and their relation to the Bridger group appear to be somewhat obscure; but it seems that while part of these beds may be contemporaneous with the Bridger, the greater portion is decidedly newer, and consequently that the entire group should be classed as Upper Eocene, and regarded as forming the transition to the Miocene beds of the White River. These Uinta beds are readily distinguished from the Bridger group by the absence of the remains of Dinocerata; and their fauna of Perissodactyle Ungulates is described as being intermediate between that of the Bridger Eocene and the White River Miocene. The genera of mammals which the authors record from these beds include (1) *Mesonyx* and (2) *Miacis* among the Carnivorous types, (3) the Rodent *Plesiarctomys*, (4) the Lemuroid *Hyopsodus*, in the Artiodactyle Ungulates (5) *Protoreodon*, and (6) *Leptotragulus*, and in the Perissodactyles (7) *Diplacodon*, (8) *Isectolophus*, (9) *Triplopus*, (10) *Pachynolophus*,[2] and (11) *Amynodon*. Of these genera, Nos. 5, 6, and 7 are peculiar to the Uinta beds, while all the others are represented in the underlying Bridger group.

Of the forms described in Parts II. and III., we shall merely notice a few of those which are of more especial interest. The first of these is the Rodent genus *Plesiarctomys*, first described by Bravard upon the evidence of very fragmentary remains from the European Tertiaries, but now fully known through the specimens described in this memoir. Dr. Scott regards this form as one of, if not actually the oldest of the known Rodents, and as therefore entitled to especial interest from an evolutionary point of view. He finds that the molar teeth (Fig. 1) are of the tritubercular type so characteristic of the earlier

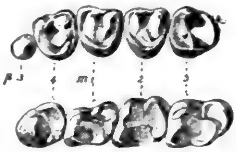

FIG. 1.—The left upper and lower cheek-teeth of *Plesiarctomys sciuroides*.

Eocene mammals of all orders (see NATURE, vol. xli. p. 465), and therefore concludes that the Rodents were probably derived from the same generalized group of mammals which has given origin to the existing Carnivora and Ungulata. *Plesiarctomys* itself should apparently be placed among the existing Sciuromorpha (squirrels and marmots), although in certain generalized features of the skull it shows signs of affinity with the Hystricomorpha (porcupines).

Another form of considerable interest is the genus *Leptotragulus*, a small Ungulate at first regarded as allied to the existing chevrotains (Tragulina), but which proves to be the earliest definitely known ancestral type of the camels and llamas (Tylopoda). This genus is indeed now regarded as the direct ancestor of *Poëbrotherium* of the overlying White River Miocene, the latter being an early cameloid type not larger than a fox; and thus affords another example of the rule that all groups of mammals increase in the size of their representatives with the advance of time. Other observations induce the author to suggest that these early Cameloid types may themselves have originally branched off from the little *Dichobunus* of the Eocene of Europe and probably also of America—a small chevrotain-like Ungulate, with bunodont molars carrying five cusps on their crowns. If this full phylogeny be substantiated by later researches it will be of extreme interest.

The Artiodactyle Ungulate described as *Protoreodon* is another annectant genus of more than ordinary interest. Thus while it conforms to the Miocene Oreodonts in the structure of the feet, and in the peculiar feature that the first lower premolar assumes the form and functions of a canine, its upper molar teeth differ in that they have five instead of four cusps on the crown, and thus accord with those of the generalized hog-like Ungulates known as *Anthracotherium* and *Hyopotamus*. This is a very important fact pointing very strongly to the derivation of the Oreodonts from an early stock more or less closely allied to the known *Anthracotheriidæ*.

With the Perissodactyla we come to the work of Prof. Osborn, and some important observations are made, in the introductory portion of Part III., regarding the synonymy of some of the earlier forms of the ancestors of the horse. It is there stated that Prof. Marsh's genus *Eohippus* is identical with Owen's *Hyracotherium* of the London Clay, from which *Pliolophus* appears to be likewise inseparable. The distinctive feature of this genus is that the fourth premolar in both jaws is unlike the first molar, the fourth upper premolar having but a single inner cusp. *Orohippus*, however, which has been hitherto identified with *Hyracotherium*, is shown to be distinct, the fourth premolar being as complex as the true molars; this genus is, however, identical with the European *Pachynolophus*. *Epihippus*, in which both the third and fourth premolars become like the molars, forms the next step in the ancestry of the horse, leading on to the well-known European genera

[1] "The Mammalia of the Uinta Formation." By W. B. Scott and H. F. Osborn. Transactions of the American Philosophical Society, Ser. 2, Vol. XVI., Part III. Pp. 111, plates 5. and woodcuts. (Philadelphia, 1889.)
[2] Incorrectly *Orotherium* in the text.

Anchilophus and *Anchitherium*. An interesting section is devoted to the rhinoceros-like animals described under the names of *Amynodon* and *Metamynodon*, the latter occurring in the White River Miocene. These genera are regarded as representing a distinct family, distinguished from the living rhinoceroses, among other features, by the resemblance of the last upper molar to the two preceding teeth. We are scarcely disposed to regard this and the other features mentioned as of sufficient importance to justify the formation of a distinct family, but this is purely a matter of opinion. *Amynodon* has been generally regarded as the ancestor of the modern rhinoceroses, but Prof. Osborn points out several objections to this view, and also shows that *Metamynodon* is clearly a separate branch from *Amynodon*, departing still more widely from the modern rhinoceroses. It is suggested, however, that the real ancestor of the latter will prove to be more or less closely allied to *Amynodon*.

Of the other Perissodactyles described in the third part, it will suffice to mention that *Isectolophus* is regarded

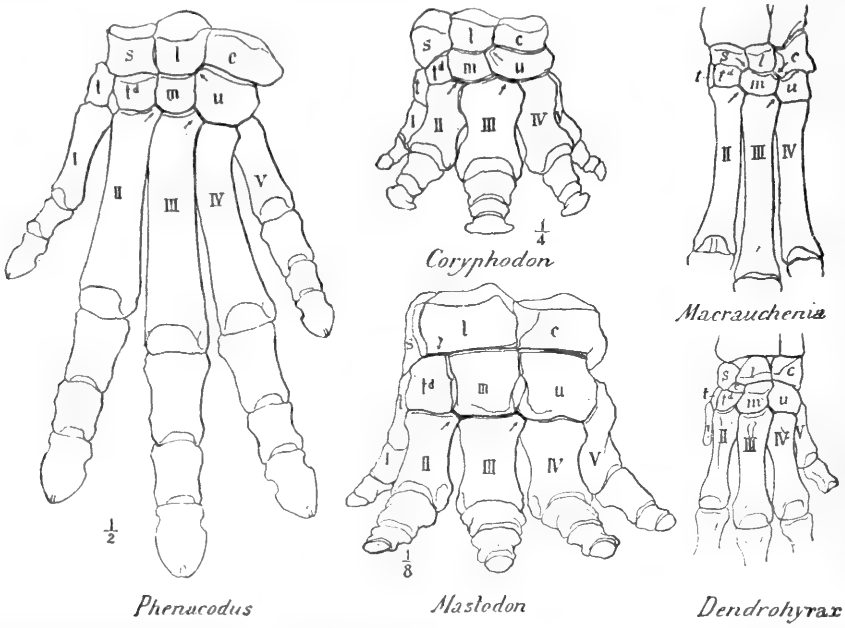

FIG. 2.—The left fore-foot of various Ungulates, to show the more generalized condition, in which the scaphoid (*s*), lunar (*l*), and cuneiform (*c*), are respectively placed directly over the trapezoid (t^d), magnum (*m*), and unciform (*u*). In *Mastodon* the lunar has extended over the trapezoid. *t* = trapezium.

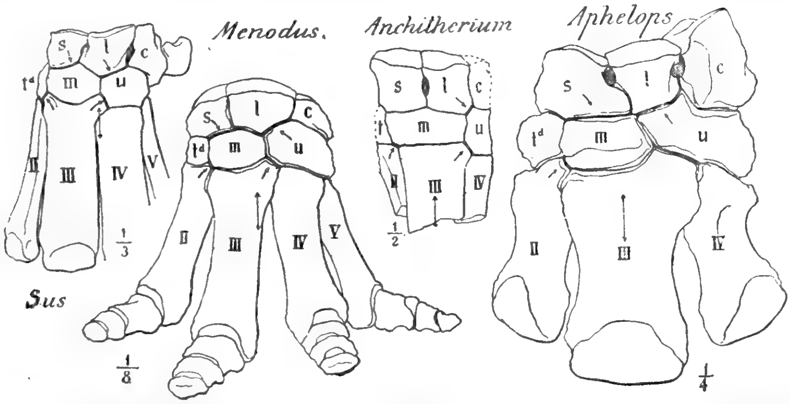

FIG. 3.—The left fore-foot of more specialized Ungulates, showing the displacement and mutual interlocking of the carpal bones. Letters as in Fig. 2. The vertical arrows indicate the median line of the foot, and the oblique ones the direction of displacement.

as an ancestral type of the tapirs, in which the fourth, and probably the third, upper premolar approximated to the type of the molars. The author considers that an imperfectly known tapiroid from the White River Miocene will prove to have three upper premolars of a molariform type, and would thus lead on closely to the true tapirs, in which all the premolars are molariform.

These observations show that in each of the three existing families of Perissodactyles there is a gradual advance in the complexity of the premolars, till in all the living types they become as complex as the molars.

In the concluding part, relating to the advance from a plantigrade and pentadactylate type of foot in the Ungulate to the digitigrade type with a reduced number of digits, Prof. Osborn lays great stress on the effects of strain and impact as leading to the gradual displacement and thence abortion of the lateral elements in the wrist, ankle, hand, and foot, supporting his conclusions with several diagrammatic figures, of which we reproduce two. The author observes that the feet of the modern Ungulates are connected with the simple type of foot found in the Ungulates of the Puerco Eocene by the genus *Phenacodus*, and that without this annectant form it would have been almost impossible to say that the Puerco mammals were Ungulates at all, since their feet are more like those of the plantigrade Carnivores. The details of how the foot of the generalized primitive type has become gradually modified into the numerous modifications exhibited by the Ungulates of the present day, are far too technical and complicated to be even touched upon in these pages, and we must therefore refer the reader desirous of entering upon this difficult branch of study to the memoir itself. We may, however, mention that the primitive type of foot (Fig. 2) is characterized by the component bones of the two horizontal rows of the wrist and ankle being placed vertically one above another, over the axes of the digits they respectively support; while in the specialized types (Fig. 3) these bones mutually overlap and interlock, so as to totally obliterate the original vertical lines of division coinciding with the intervals between the individual digits. The nearest approach to the primitive type now remaining, is found in the elephant and the hyrax; but the elephant and its ally the mastodon (Fig. 2) are peculiar in that the lunar bone of the wrist has become extended towards the outer side so as to rest upon the trapezoid.

In conclusion, we may observe that a memoir like the present marks a distinct advance in our knowledge, not only of the mammals of the Upper Eocene of North America, but also in respect to several points in connection with the phylogeny of the Ungulates, and of the relationship of the extinct Old World representatives of that order to those of the new. We offer our congratulations to the authors, and look forward to seeing equally good work on the mammals of other horizons of the Tertiaries of the United States. R. L.

EARTHWORMS.

THE Colonial Office can hardly render a greater assistance to science, than by publishing such reports from our distant possessions as that contained in the October number of the *Kew Bulletin*, from Mr. Alvan Millson, Assistant Colonial Secretary at Lagos, who has also acted as a Special Commissioner to the interior, and who has made good use of his opportunities in observing Nature in those remote parts.

The report in question is contained in a despatch from Sir Alfred Maloney to Lord Knutsford, dated June 11, 1890, and we propose to give a short account of its contents.

In Yoruba Land, after passing the fringe of forest, which skirts the lagoons to the eastward of Lagos for some 50 miles inland, a vast tract of open country is reached, extending as far as the valley of the Niger and the Houssa States beyond. The only difference between these grass lands and the forest fringing the lagoons appears to be that "for many generations the farmers of Yoruba have with axe and fire destroyed the growing trees, and robbed the soil of its original covering, leaving nothing but a rank growth of tall and tangled grass to take its place." This is apparently unfavourable to the growth of deep-rooting trees, but shows a truly surprising surface-fertility, when subjected to cultivation; and as the Yoruba people are cut off from the coast by the tribes inhabiting the forest belt, and are entirely dependent on the soil for food and clothing, it has to support a considerable population.

The soil appears to consist of a sandy loam derived from the igneous rocks, ironstone or quartz conglomerate, which form the bed rock, the soil increasing in fertility where the harder strata give place to more friable micaceous rocks, but even where the soil is not over a foot in depth, the fertility is truly astonishing. Crops in Yoruba are not only of unusual excellence, but the surface soil shows a marvellous recuperative power, even when compared with that of favoured lands in other portions of the tropics.

In this district, after a very simple tillage with the hoe only, the following rotation of crops is raised. In the first year a crop of yams and Indian corn is planted, and a second crop of maize and beans in the autumn; the same in the second year; while in the third year both crops are maize and beans. No manure of any kind is used, nor any tool more powerful than the hoe; and then for two or three years the land lies fallow, after which it is ready for a similar rotation, and so on. A crop of Guinea corn, cotton, indigo, tobacco, and sweet potatoes is also in some places gathered.

In spite of the exhaustive system of cultivation pursued, the crops show no sign of falling off, and such is the inexhaustible fertility of this belt, that maize sells for 4½*d.* and sweet potatoes at 1*d.* per 70 pound load, and other products in proportion, even in large towns like Ibadau, said to have 150,000 inhabitants.

Mr. Millson considers that the fertility cannot be caused by termites, as described by Drummond in "Tropical Africa," as the ant-hills of the Yoruba land are exceptionally small and widely scattered; and visiting the country only in the wet season, it would appear impossible to account for the unusual fertility. In the dry season the mystery is at once solved, in a very simple and, Mr. Millson considers, in a most unexpected manner; although, taking into account the universal presence of the earthworm, both in temperate and tropical climates, we think there is little reason for surprise; but we do not remember to have heard of a more marked instance of the importance of small agencies in effecting great results.

Mr. Millson continues:—"The whole surface of the ground, among the grass, is seen to be covered by serried ranks of cylindrical worm-casts, varying from a quarter of an inch to 3 inches, and existing in astonishing numbers. For scores of miles they cover the land, closely packed, upright, and burnt by the sun into rigid rolls of hardened clay, which stand until the rain breaks them down into a fine powder. . . . On digging down, the soil is found to be drilled in all directions by countless multitudes of worm-drills; while from 13 inches to 2 feet in depth the worms are found in great numbers in the moist subsoil."

Mr. Millson estimates that the worm-casts, in one season, average over 5 pounds per square foot of soil; and at this estimate, which he considers very moderate, the annual result of the work done by the earthworms of Yoruba gives a total of not less than 62,233 tons of subsoil brought to the surface in each square mile of cultivated land every year. "This work goes on unceasingly year after year, and to the untiring labours of its earthworms this part of West Africa owes the livelihood of its people. Where the worms do not work, the Yoruba knows that it is useless to make his farm."

Mr. Millson estimates that every particle of earth in each ton of soil, to the depth of 2 feet, is brought to the surface once in twenty-seven years, which gives an average of 0·88 inch per annum, or four times as much as Darwin estimated ("Earthworms," p. 130) to be the case in the experiments tried at Maer Hall; but on the Nilgiries, worm-casts are found to average 3 ounces each, the largest weighing 4¾ ounces (*ibid.*, p. 129). We have, therefore, little doubt that Mr. Millson's estimate of the movement of soil is quite probable.

Mr. Millson considers that, most probably, the comparative freedom of this part of West Africa from dangerous malarial fevers is due, in part at least, to the work of the earthworms in ventilating and constantly bringing to the surface the soil in which the malarial germs live and breed. Darwin (*ibid.*, p. 239) remarked that the disappearance of organic matter from mould was probably much aided by its being brought again and again to the surface in the castings of worms, and this would account for the absence of malarial fevers.

The worms sent home by Mr. Millson have been submitted to Mr. F. E. Beddard, who reports that they belong to a probably new species of the genus *Siphonogaster*.

We trust that Mr. Millson will continue to send home further accounts of his valuable observations, and that the example he has set will be followed by others stationed in our colonies. S. N. C.

MUSEUMS FOR PUBLIC SCHOOLS.

ALL teachers, I have no doubt, have experienced the refreshing interest that boys and girls take in objects of natural history. And not in natural history merely, for whenever the lesson, no matter what it is about, admits of being illustrated by specimens, then the presence of these specimens gives a point to the description and produces an effect that otherwise would be wanting. Take your young audience in imagination into the country or to the seaside, and show the nest and bird, insect, plant, seaweed, or crab you are describing, and you know you can sustain their attention throughout. It is equally certain, too, that, in describing the characteristics of any particular place, it is desirable to be able to indicate by something more than the bare statement what is meant by "solan-geese and other sea-fowl," and such expressions. How vague often are the ideas produced by the words ruby, marble, granite, isinglass, and other "articles of produce," even though well described, when the actual article itself is bound to implant the nature of the object in the pupil's mind, and the description at the same time. How much could be taught in a very agreeable way, moreover, with a series of specimens exhibiting the manufacture of certain important fabrics from the raw material, and especially those that are made in the immediate district of the school.

It will be generally admitted, I think, that schools should be provided with the means of giving such instruction: the difficulty is, how can it be done? Suggestions have been made on several occasions that the specimens in our public museums should be made available for the purpose. Dr. James Colville, in a paper on "Public Museums as Aids in Teaching,"[1] has pointed out that he is allowed to draw upon the Glasgow Museum for specimens. In Liverpool, alone, however, as far as I know, is the circulation of museum objects carried out in a satisfactory and systematic manner. A good account of the method is given in a pamphlet on a "Proposed Circulating Museum for Schools and other Educational Purposes," by the Rev. Henry H. Higgins, published in 1884; and in the Report which was issued by Mr. Thomas J. Moore, the Curator, later in the same year. The Museum distributes a series of boxes of specimens, and these are removed from school to school at stated intervals.

In many districts, however, and especially where the public Museum is more or less remote, the system so generously inaugurated by the Liverpool Museum will not be found available. In some of our large provincial towns, indeed, where there is a Museum, such a scheme could not be carried out without a great extension of the work of the Museum, for which there is at present no provision. Where this is so, and alas, it is quite general, an attempt is made in many of our schools to gather together what must necessarily be a desultory and very limited collection. I am afraid that few schools, indeed, can show such a typical series of natural history specimens as that sketched by Prof. Flower in NATURE (vol. xli. p. 177).

Here, then, is a good work for the secondary schools which are now and again springing up all over the country. In each of these academies and high schools there is a science department, which, besides its chemical apparatus and the like, can boast, no doubt, of a number of objects gathered at random. And though these may be far more numerous than the specimens to be seen in the ordinary school in the next street, still, how far is the collection from being systematic and typical! The specimens are usually kept, moreover, in drawers, and at any rate with little attempt to display, arrange, or name them. But were the facilities for gathering specimens increased; were a room set apart and furnished with cases for their reception; were, in fact, the secondary school encouraged to get together a double series of objects—one for circulation in the surrounding district, and one for its own use—the benefits now being enjoyed in Liverpool might be extended to other towns without waiting for the public Museum to take the matter up. For each town, in this way, one or two reasonably typical collections, including actual specimens, models, and diagrams, would be provided; and the amount expended at present in individual endeavours would go far towards having this done with considerable completeness.

A good outline of what should be aimed at in such a museum is given in the article by Prof. W. H. Flower, cited above. He has also contributed a series of papers on "Methods," which will be found of the utmost service (NATURE, vol. xv. pp. 144, 184, 204); and it will be seen from these latter that it is quite possible to prepare a great portion of the museum in the school. Still, no better model could be copied than that provided at Liverpool, both as regards the choice of the specimens, and the method of circulating them. The pamphlets referred to above contain information on both points. I should only take the opportunity of recommending that which I have incidentally mentioned in the opening sentences, viz. the addition of important articles of commerce and manufacture.

With such a museum at the disposal of our schools, and provision made for its growth, and the display of a duplicate series of specimens in the secondary school itself, the results of our teaching would be far more real and lasting, and we might now and then touch a sympathetic chord, and awaken an interest having a lifelong influence. ALEXR. MEEK.

University College, Dundee.

[1] Read before the Philosophical Society of Glasgow in 1888.

JAMES CROLL, F.R.S.

BY the death of this well-known writer geological literature loses one of its most voluminous and able contributors Though not in the proper sense of the word a geologist, he had made himself well acquainted with many geological problems, and first attracted notice more than five-and-twenty years ago by the brilliance and suggestiveness of his attempts to solve them. He was born in 1821 at Little Whitefield, in Perthshire, and after the usual brief schooling of a peasant's son he was apprenticed as a millwright in his native village. The employment allowed him leisure for reading, and he devoted himself with ardour to the study of philosophy and of physical science. At the age of twenty-four, however, the effects of an accident which he had met with in boyhood compelled him to seek a less laborious vocation, and eventually he became agent for an insurance company. These early years gave but little promise of the particular bent of his genius by which he would attain distinction. Eventually his general acquirements and the zeal with which he was known to devote his spare time to philosophical reading attracted the interest of the governing body of the Andersonian University and Museum in Glasgow, and in 1859 he was appointed keeper at that establishment. He had already found his way into print by publishing anonymously a volume on the "Philosophy of Theism." But his new position in an institution devoted largely to the teaching of science led him to throw himself more fully into the study of physics. In 1861 he published, in the *Philosophical Magazine*, his first contribution to scientific literature—a paper on an electrical experiment of Ampère's.

About that time the Geological Society of Glasgow was founded, and became the centre of an active company of geologists who specially took up the study of the traces of the Glacial period, so striking and abundant in the west of Scotland. Croll was drawn into the prevalent enthusiasm, and soon with characteristic ardour and acumen began an investigation of some of the physical difficulties which had arisen in the course of geological inquiry. In 1864 he published his remarkable essay, "On the Physical Cause of the Change of Climate during the Glacial Epoch." This paper speedily attracted the notice of men of science. In it the author endeavoured to find a true cause for the extension of snow and ice during the Ice Age far beyond their present limits. For this purpose he invoked the aid of astronomical and terrestrial physics, and he provided an explanation which captivated geologists by its simplicity as well as by the wide range of phenomena which it helped to elucidate.

It was this paper which laid the foundation of his scientific reputation. It was likewise the means of opening up for him a new and more congenial employment, for it led to his being selected by the present Director-General of the Geological Survey to take charge of the maps and correspondence of the Survey in Edinburgh. He was appointed to this office in 1867, and found himself able to prosecute with more vigour than ever the researches in physical geology which had now so great a charm for him. The question of the origin of climate led him into a far wider field of investigation than he had at first contemplated. It brought him face to face with many theoretical problems which geologists had been unable to solve. These he attacked with characteristic energy. He enforced his arguments with a single eye to the discovery and establishment of truth, and exposed without reserve views which seemed to him erroneous. With no intention of rousing controversy, he soon found himself in collision with other writers who disputed his arguments. One of the most interesting and vigorous of these disputations was with the late Dr. W. B. Carpenter, regarding the theory of Oceanic Circulation. Croll maintained with great force and with general approbation the position for which he contended, that the prime motors in the circulation of the ocean were the winds. After publishing many papers on this and cognate subjects, he collected, condensed, and partly re-wrote these, adding fresh materials to them, and issuing the whole as his well-known work on "Climate and Time in their Geological Relations," which appeared in 1875. Though much division of opinion was aroused as to the real value of some of his views in relation to the establishment of sound geological theory, there was a general recognition of the originality and acuteness of his mode of dealing with accepted facts and principles, and of the value of his writings as stimulating and directing inquiry. He was accordingly elected a Fellow of the Royal Society in 1876, and the University of St. Andrews conferred on him the degree of LL.D.

By degrees, however, Dr. Croll's health began to fail. He suffered so intensely from pains in the head that he was compelled, in 1881, to resign his appointment in the Geological Survey, and retire on the miserably small pension to which, by the rigid rules of the Civil Service, his length of service only entitled him. By exercising the greatest care he was still able at intervals to resume his studies in geological physics, and to publish occasional papers, partly in reply to his critics, who were now increasing in number and pertinacity. In 1885 he published a smaller volume embracing some of these papers, and much new material under the title of "Discussions in Climate and Cosmology."

Dr. Croll's investigations into the geological history of terrestrial climate had led him to consider the question of the origin of the sun's heat, and thence to reflect on the probable condition and development of nebulæ and stars. The later chapters of the volume just mentioned were devoted to these subjects, which he would fain have discussed more at length, had not the increasing failure of his bodily powers warned him that, if he wished still to return to that philosophy which was his first love, he must husband his remaining strength. Nevertheless, the attraction of these astronomical problems proved insuperable. He continued to work at them, gradually enlarging the scope of the investigation until it embraced not the earth and the sun merely, but the origin and development of the whole material universe. At last he followed his usual method, gathered together his various contributions to the subject, trimmed, enlarged, and modified them, and published them in a separate volume, entitled "Stellar Evolution and its Relation to Geological Time."

The publication of that work marks the close of his labours in more definitely scientific inquiry. He was now free, with such remaining strength as he could command, to re-enter the field of philosophical speculation in which he had spent his earliest years of mental exertion, and which for nearly thirty years, through all the engrossing attractions of geological inquiry, had never lost its fascination for him. Accordingly he betook himself once more to the study of such subjects as Force, Matter, Causation, Determinism, Evolution, and proceeded to apply the facts and principles with which he had in the interval been dealing so actively to the problems in philosophy that had aroused his thoughts in the early years of his life. In spite of his increasing infirmity, he persevered in committing to writing the ideas which he had now matured, and this year he sent to press his last work, published only a few weeks ago, "The Philosophical Basis of Evolution."

Of all recent writers who have contributed so much to current scientific literature, probably no one was personally so little known as Dr. Croll. His retiring nature kept him for the most part in the privacy of his own home. But he endeared himself to those who were privileged with his friendship by his gentleness and courtesy, his readiness to help, and the quiet enthusiasm with which he would talk about the topics which absorbed his thoughts. After quitting the Geological Survey of Scotland he tried residence at different places in hopes of finding one where his failing bodily health would least impede the powers of his mind, which he retained with singular freshness up to the close. He settled at last in the town of Perth, where he spent the few remaining years of his life. Struggling on in spite of several ominous warnings, he finished his last book just before the final stroke which carried him off on Monday, the 15th inst.

A. G.

NOTES.

THE President of the Board of Trade has appointed a Committee, to consider whether any, and if so what, steps should be taken for the provision of electrical standards. The following are the members of the Committee:—Lord Rayleigh and Sir William Thomson (representing the Royal Society), Prof. G. Carey Foster and Mr. R. T. Glazebrook (representing the British Association for the Advancement of Science), Dr. John Hopkinson and Prof. W. E. Ayrton (representing the Institution of Electrical Engineers), Mr. E. Graves and Mr. W. H. Preece (representing the General Post Office), Mr. Courtenay Boyle and Major P. Cardew, R.E. (representing the Board of Trade).

The first meeting of the Committee will be held at the Board of Trade on Thursday, January 15. Sir Thomas Blomefield, of the Board of Trade, will act as secretary to the Committee.

There ought to be no doubt as to the response to the appeal which has been addressed to Lord Salisbury with respect to Egyptian monuments. As everyone knows, they are among the most interesting monuments in the world, and it is scandalous that they should be exposed to wanton injury. The signatures to the memorial include many eminent names, and we may hope that a suitable inspector will speedily be appointed.

The Medical Faculty of University College, Dundee, St. Andrews University, in conjunction with the Royal Infirmary of that city, have appointed Prof. Percy Frankland and Dr. Stalker as delegates to visit Berlin in order to study Dr. Koch's new method for the treatment of tuberculosis.

The committee appointed by the Royal Horticultural Society to consider the best way of doing honour to the memory of the late Mr. Shirley Hibberd met on December 19. They unanimously decided that a portrait of Mr. Hibberd should be secured, and placed in the hands of the trustees of the Lindley Library, on behalf of the Royal Horticultural Society. Any surplus that may remain after the payment of expenses connected with the preparation of the portrait is to be invested for the benefit of Mr. Hibberd's orphan daughter. Dr. Masters is chairman of the committee appointed to carry out the scheme.

The Lord President of the Council has appointed Dr. C. Le Neve Foster, Inspector of Mines under the Home Office, Professor of Mining in the Royal College of Science, London.

The Board of Agriculture has approved of the scheme for establishing a Chair of Agriculture at the Yorkshire College, and it has been decided that a Professor shall be appointed at a salary of £300, with emoluments in addition.

In an interesting pamphlet on agricultural education, Mr. P. McConnell, Lecturer on Agricultural Science at Balliol College, Oxford, refers to the supposed want of teachers competent to teach scientific farming. In his own experience in the matter—and it has not been little—he has found that there is no such want. On the contrary, he says, the great want is the want of students to be taught by such teachers as we have. He contends that agricultural science can be taught at any College where there is already a science curriculum, and that, in fact, "it is only there that we can hope to have the matter developed on a system cheap enough to have it brought within the reach of ordinary farmers."

The following are the probable arrangements for scientific lectures at the Friday evening meetings at the Royal Institution before Easter 1891:—January 23, Lord Rayleigh, F.R.S., some applications of photography; January 30, Lord Justice Fry, British mosses; February 6, Prof. J. W. Judd, F.R.S., the rejuvenescence of crystals; February 13, Prof. A. Schüster, F.R.S., some results of recent eclipse expeditions; February 20, Edward Emanuel Klein, F.R.S., infectious diseases, their nature, cause, and mode of spread; March 6, Prof. Dr. J. A. Fleming, electro-magnetic repulsion; March 20, Prof. W. E. Ayrton, F.R.S., electric meters, motors, and money matters.

Prof. Dewar will deliver at the Royal Institution a course of six lectures (adapted to a juvenile auditory) on frost and fire, on the following days, at three o'clock:—Saturday, December 27, Tuesday, December 30, Thursday, January 1, Saturday, January 3, Tuesday, January 6, Thursday, January 8.

Messrs. Newton and Co. are making for the Royal Institution a new electric lantern, which will be first used in Prof. Dewar's Christmas lectures. The arc light is fixed on an adjusting table, and the body of the lantern revolves so as to bring any one of the fronts opposite the fixed light.

Mr. C. Callaway, D.Sc. (Lond.), has been directed by the Shropshire County Council to inquire into the needs of the county with regard to scientific instruction, and to present to the Technical Education Committee of the Council a report on the subject.

In the *Kew Bulletin* for December there is a letter from Mr. G. T. Carter, C.M.G., on the attempts which have been made to develop the agricultural industries at the Gambia. It affords, as the *Bulletin* observes, striking evidence of the almost insuperable physical difficulties which stand in the way of the permanent success of such efforts. The *Bulletin* notes that by the West African agreement between Great Britain and France of August 10, 1887, a frontier line between the English and French possessions was established. In accordance with its provisions a Special Commission of Delimitation was appointed to trace upon the spot the line of demarcation between the English and French territory. The partition of tropical Africa amongst European nations has made it more than ever a matter of importance to procure materials for, at any rate, a rough survey of its botanical resources. It was desirable to use the opportunity presented by the Gambia Delimitation Commission for the purpose. The Colonial Office was, however, unable to find the funds for attaching a botanist to the staff. But they were willing to allow a medical officer to be selected who would do what was possible in the way of botanical exploration. The appointment was accepted by Mr. J. Brown-Lester, M.B., C.M., of the University of Edinburgh. He was supplied with the necessary botanical outfit from Kew, and left Liverpool with the expedition in the s.s. *Congo* on November 15.

In addition to the section on cultural industries at the Gambia, the *Kew Bulletin* for December contains much valuable information on the production of prunes in the south of France, the cultivation of perfumery plants in the colonies, banana disease in Fiji, and fibre productions in the Caicos.

We are glad to see that the City Commission of Sewers are devoting serious attention to the smoke nuisance. At a recent meeting the Sanitary Committee brought up a report relating to frequent complaints on the subject in the City. They stated that for years past Bills had been introduced into Parliament giving local authorities greater powers to deal with such cases, but none of these measures had become law. They recommended that in the next suitable instance a prosecution should be directed against the offenders. Dr. Sedgwick Saunders, medical officer of health, said he had seen the experiments on the Embankment which were being conducted by Mr. Elliott, of Newbury, and the results were eminently satisfactory, especially so far as they related to smoke from furnaces and shafts. They were not so satisfactory in regard to domestic fires. The report was carried, and the Sanitary Committee was directed to investigate and consider the best means of abating the smoke nuisance, and to report thereon to the Commission.

According to a telegram from San Francisco, there has recently been an eruption of the volcano at Macao.

The Report of the Meteorological Council for the year ending March 31, 1890, shows that the work included under the three departments—ocean meteorology, weather telegraphy, and meteorology of the British Isles—is actively carried on. Owing to the want of information in the Pacific, which was felt on the occasion of the Samoa cyclone in March 1889, the Council have decided to establish stations on some of the islands there, with the view of obtaining further observations. The information received by telegraph as to the state of the weather on the British coasts is now conspicuously displayed outside the office twice daily for the use of the public. Among the various reports issued, the Weekly Weather Report merits special mention, as it supplies a very complete and instructive view of the weather changes day by day over the greater part of Europe. Among the various experiments which have been carried out may be mentioned those for determining the pressure of wind on plates of various sizes and inclined at different angles. These experiments have been made with great skill by Mr. W. H. Dines, and the results have been partially published. The determination of solar radiation is a matter upon which considerable uncertainty exists, as no two instruments can be depended upon for giving similar results under similar circumstances. Experiments with two sets of Violle's actinometer apparatus, consisting of *boules conjuguées*, or two hollow copper spheres, one coated with lamp-black and the other gilt, surrounding the bulbs of two thermometers precisely similar in all respects, have been under trial at Kew Observatory, with the view of determining whether their relative values are constant. The result of the experiment is not yet published. The Report tates that there are about 11,000 volumes and pamphlets in the library, containing meteorological data from all parts of the world. The books and other documents are accessible to scientific men for reference at the Meteorological Office; and to facilitate inquiry, reference catalogues are prepared both under authors and subjects.

ONE of the decisions of the last Congress of Russian Naturalists was to the effect that a *Meteorological Review* should be published in Russian, under the direction of the Academy of Sciences. The first volume has been issued, and contains several valuable papers, namely:—On the comparison of the normal barometers of the West European Observatories, by A. Shenrock; on the average temperatures which can be deduced from observations of the maximum and minimum thermometers, by E. Leist; on magnetic observations in Caucasia, by E. Assafrey; and on the Lena, by E. Stelling; on the thunderstorms in Russia in 1886, by E. Berg (9544 observations at 549 different places having been taken into consideration); and on the accumulations of snow on Russian railways, by B. Sreznevski.

THE Board of Editors at the Columbia College, New York, have decided to publish in January the first number of a monthly review, which will be devoted to "the scientific study and discussion of education." It will be known as the *Educational Review*, and will include within its scope education of every grade, higher, secondary, and primary. Each number will contain signed articles on topics of current interest, critical notes and discussions on educational subjects, "an account of important movements in educational thought throughout the world, and results of contemporary psychological research so far as the same have an educational significance."

AN important work on Russian ethnography is being published by A. Pypin. The first volume contains the history of ethnographical research in Russia, and deals with the ethnography of the great Russian stem.

STUDENTS of ethnography will be sorry to hear that Adrian Jacobsen, who has done so much good service by the ethnographical collections he has brought together, finds his scientific labours so unprofitable from a material point of view that he is compelled to abandon them. The attention of Dr. Bastian was attracted to Jacobsen by a most valuable collection he had formed in Greenland, Lapland, Labrador, and elsewhere in 1876–80. The Ethnological Committee founded by Dr. Bastian commissioned Jacobsen to collect objects for the Berlin "Museum für Völkerkunde"; and from 1881 to 1883 he devoted himself to the accomplishment of his task, bringing back to Berlin from the north-western regions of America no fewer than 8000 specimens. In the same service he travelled in 1884 and 1885 among the peoples of Eastern Russia and in many parts of Asia, returning with 3000 objects of great interest; and in the course of a third journey, in 1887 and 1888, he secured 5000 specimens in Singapore, Java, Celebes, and other regions. There are about 90,000 objects in the Berlin Museum, and more than one-sixth of them have been obtained by this skilful and enthusiastic collector, whose devotion to his chosen mission has often placed his life in danger. *Globus*, by which these facts are recorded, finds it hard to believe that "for such a man Germany has no further work and no further gratitude."

La Nature records an interesting archæological discovery which has lately been made near Apt, in Vaucluse, in the valley of the Caulon. M. Rousset, a retired inspector of forests, while superintending the digging of a ditch, was lucky enough to find, on a bed of pebbles, at a depth of 2·50 metres, the remains of what seems to have been a prehistoric workshop. The flint implements had such sharp edges, and were generally in so excellent a state of preservation, that they had evidently never been disturbed from the time when they had been chipped into shape. Among the objects were three nuclei, and students who have been examining them have succeeded in reuniting with each nucleus the fragments broken from it. Thus it is possible to note exactly the procedure of the prehistoric workmen.

M. EDOUARD MARBEAU contributes to the current number of the *Revue Française de l'Étranger et des Colonies* an instructive paper on what he calls "the depopulation of France." From Prof. Léon Le Fort he quotes the following comparison between France and other European countries. For every group of 1000 inhabitants there are born in Hungary 42 children; in Germany, 39; in England, 35; in France, 25. In 1778 the number in France was 38·4. At the present rate of increase, the population would be doubled in Saxony in 45 years; in England in 52 years; in Prussia, in 54 years; in France, in 198 years. If the period of 1886–89 were taken, the time for the doubling of the French population would be 349 years. The slow rate of increase excites much anxiety among thoughtful Frenchmen. It compels them, as M. Marbeau says, to regard "the foreign invasion" as a benefit. At the last census, there were in France 1,137,037 foreigners, three times as many as were to be found in England and Germany combined. These immigrants come chiefly from Belgium, Germany, Italy, and Spain. Recent inquiries show that only 408,000 persons of French birth are living out of France. Of these, 50,000 are in Switzerland; 26,000 in England; 17,000 in Spain; 10,000 in Italy; 55,000 in Belgium; 100,000 in the United States; 60,000 in La Plata.

THE eighteenth fasciculus of M. Fabre's "Traité Encyclopédique de Photographie" (Gauthier-Villars) gives a very useful and interesting account of the methods employed in astronomical photography of every description, and the decisions of the International Star-charting Congress.

DR. G. B. LONGSTAFF'S "Studies in Statistics, Social, Political, and Medical," will be issued by Mr. Edward Stanford on January 12.

THE following science lectures will be given at the Royal Victoria Hall during January:—January 6, the moon, by Dr. Fleming; January 13, glaciers, by Prof. A. H. Green; January 20, our bodies, by Dr. P. H. Carpenter; January 27, all about spectacles, by Dr. Collins.

AT a recent meeting of the Asiatic Society of Japan, held at Yokohama, Admiral Belknap, of the United States Navy, read a paper on the depths of the Pacific Ocean. Admiral Belknap was in Japan in 1874, in command of the U.S.S. *Tuscarora*, engaged in surveying the proposed route for a Pacific submarine cable. The greatest depth found on the voyage was 3287 fathoms, and H.M.S. *Challenger*, then on her exploring voyage, had not discovered anything in the Pacific of as great a depth. But upon leaving Yokohama the *Tuscarora* made very deep soundings. Only 100 miles from the coast 3427 fathoms were found, and a little further on 4643 fathoms went out without bottom being touched. Still keeping on the great circle track a number of soundings of over 4000 fathoms were made, the deepest being 4655. After re-coaling at Hakodate a fresh departure was made, and the Kuriles were skirted, and here again very deep water was found, except in one place, where there is a ridge of land on which there was only 1777 fathoms, whilst there was 3754 on the western side of it, and 4037 on the eastern side, only eighty miles from land. Admiral Belknap observed that there is, therefore, evidently a deep submarine valley running parallel with the coast of Japan, and some 250 miles in width. Whether the Kuro Siwo, or Japan current, corresponding in a sense to the Gulf Stream, has anything to do with this is a matter for surmise. Since the *Tuscarora* first showed us these great depths others have been discovered. The *Challenger* after leaving Japan found 3750 fathoms 200 miles east of Cape King, and nearly the same depth another 200 miles farther, after which the water shoaled. She also got 4475 fathoms only 150 miles from Guam in the Caroline Islands. The U.S.S. *Albatross* found 3820 fathoms off the coast of the Aleutians, and the U.S. Coast Survey steamer *Blake* got 4561 fathoms 70 miles north of Porto Rico, whilst H.M.S. *Egeria*, surveying in the South Pacific, has succeeded in getting depths of 4428, 4295, and 4530 fathoms. Subsequent researches have proved that the deepest portions of both the Atlantic and Pacific Oceans are close to their western shores. The Admiral then gave some description of the apparatus employed, and after paying tribute to the English and American Navies for their researches, he concluded a most interesting lecture by suggesting that the Japanese Naval Service should take up the work, more particularly on their own coasts and along the course of the Kuro Siwo.

THE additions to the Zoological Society's Gardens during the past week include a Wild Cat (*Felis catus* ♂) from Scotland, presented by Mr. Osgood H. Mackenzie; an African Cat (*Viverra civetta* ♀) from West Africa, presented by Mr. John J. Pitcairn, M.R.C.S., F.Z.S.; two Weka Rails (*Ocydromus australis*) from New Zealand, presented by Mr. Edward T. Dixon; a Common Tequexin (*Tupinambis tequexin*) from Rio de Janeiro, presented by Mr. Edward Sloane; a Himalayan Bear (*Ursus tibetanus*) from Tibet, deposited; a Molucca Deer (*Cervus moluccensis* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

STARS WITH PECULIAR SPECTRA.—A communication from Prof. E. C. Pickering to *Astronomische Nachrichten*, No. 3008, announces the discovery of the following stars having peculiar spectra, and of some new variables in the constellations Triangulum and Hydra:—

Designation of star.	R.A. 1900.	Decl. 1900.	Mag.	Date of photograph.	Description of spectrum.
	h. m.	° ′			
D.M. + 33°·470	2 31·0	+33 51	9·2	1890 Oct. 13	III. Type. Bright hydrogen lines.
Cord. G.C. 7192	5 59·4	− 6 42	5·8	1888 Feb. 15	F line bright.
,, ,, 17717	12 56·3	−70 56	6·6	1890 May 14	F line bright.
,, ,, 18770	13 43·4	−27 44	7·0	,, May 15	III. Type. Bright hydrogen lines.
,, ,, 18947	13 51·6	−55 51	8·0	,, May 25	IV. Type.
,, ,, 20554	15 48	−69 42	6·2	,, May 26	IV. Type.

It is remarked that "the stars D.M. + 33°·470 and Cord. G.C. 18770 in the above list have a spectrum in which the lines due to hydrogen are bright, as in that of *o* Ceti and other variables of long period. They were therefore suspected of variability." An examination of the Harvard College Observatory photographic charts and spectra indicates that the former star varies between 7·1 mag. and 9·2 mag., and the latter between 7·0 mag. and 10·4 mag. Three observations of Cord. G.C. 18770 by Stone gave a magnitude 6. It is interesting to note that the Rev. T. E. Espin announced the probable variability of the star D.M. + 33°·470 in *Walsingham Observatory Circular*, No. 27 (NATURE, November 13, p. 45).

A photograph of the spectrum of T Ceti shows that it belongs to the third type. A photograph of the spectrum of the variable of the Algol type, viz. S Antilæ (R.A. 9h. 27·9m., Decl. −28° 12′), discovered by Paul in 1889, shows the hydrogen lines at λ 410 and λ 434 (*h* and G) narrow, while the lines at λ 394 and λ 397 are very broad. This would place it in "an intermediate class between stars of the first and second types."

THE ROTATION OF JUPITER.—A report in the *Revue Générale des Sciences*, of the meeting of the St. Petersburg Academy of Sciences held on November 18, contains an account of a paper by M. Biolopolski, on the rotation of the planet Jupiter. Cassini appears to have been the first to point to the analogy between the rotation of Jupiter and the sun, by demonstrating that the velocity at the equator is greater than on the rest of the surface of these two bodies. It is known that on the sun the angular velocities are functions of the heliographic latitudes. By utilizing observations and drawings made by Cassini, Herschel, Schröter, and many other observers, M. Biolopolski has been able to determine more than a hundred angular velocities at various "Jovigraphic" latitudes. Among these velocities two predominate, one of 9 hours 51 minutes, and another of 9 hours 55·5 minutes (approximately). The first is found almost exclusively in the zone between 0° and 5°, in both hemispheres; the second is obtained from the remainder of the surface, except between 5° and 10°, both N. and S., where the two velocities appear to occur with equal frequency. These conclusions are confirmed by Mr. Keeler's drawings of Jupiter, made at the Lick Observatory during this year.

EDDIE'S COMET (?).—A telegram from Cape Town Observatory to the editor of the *Astronomische Nachrichten*, with regard to the supposed remarkable comet seen by Mr. Eddie on October 27 at Grahamstown, reads: "It has been cloudy here, October 27; has not been seen by anyone else."

NAMES FOR ASTEROIDS.—The following names have been given to recently-discovered asteroids:—

(283) Emma.	(289) Nenetta.
(284) Amelia.	(293) Brasilia.
(285) Regina.	(294) Felicia.

PERIOD OF χ CYGNI.—Mr. Chandler represents the inequalities in the period of the variable χ Cygni by the formula

$$406{\cdot}02\ E\ \text{days} + 0{\cdot}0075\ E^2\ \text{days} + 25^\circ{\cdot}0\ \sin\,(5^\circ\ E + 272^\circ),$$

where E is the normal epoch of a maximum. This formula, containing quadratic and periodic terms, gives the epochs of maxima much nearer than those derived from Schönfeld's uniform period of 406·5 days.

BIOLOGICAL NOTES.

ILLUSION OF WOODPECKERS AND BEARS.—Mr. J. D. Pasteur, Inspector of the Post and Telegraphic Service at Java, communicated to Dr. F. A. Jentink, in July last, the following very curious and interesting facts about woodpeckers, who, under the illusion that the buzzing sound so apparent on applying the ear to telegraph poles is caused by the vigorous efforts of gnawing or boring insects, make large holes in the timber, on a hopeless chase after such. He incloses a piece of a telegraph pole made of teakwood, with two woodpeckers (*Picus analis*), from the Kediri Residency, Java. The wood, which is of iron hardness, is perforated with rather large holes near the place where the insulators had been attached. Although Inspector Pasteur passes thousands of telegraph poles under view each year, only in a very few cases has he found any damage done to them by woodpeckers, and, until now, the damage done has always been on the living kapok trees (*Eriodendron anfractuosum*), which are used in Java for this purpose. The piece of telegraph pole now sent is the only instance known to him of damage being done to the sound and very hard poles of the teak (*Tectona grandis*). Besides the above-mentioned woodpecker, from time to time the rare little *Picus moluccensis* was seen also among the others at work. Mr. Pasteur remarks on the great rarity of such a phenomenon: in the Paris Electrical Exhibition of 1881 there was exhibited, as a great curiosity, a telegraph pole sent from Norway, which was perforated by a hole of 7 centimetres in diameter. The Norwegian Administration was for a long time uncertain to what cause to ascribe this damage done to poles, which were otherwise quite sound, till a mere chance at last revealed woodpeckers at work. In Norway, too, another equally remarkable case of damage had been noted as done to telegraph poles by the large stones, which are heaped round their base to insure their stability in the ground, being removed and scattered, apparently without any reason. This, which was for a length of time inexplicable, was at last found to be the work of bears, who apparently mistook the sound in the timber for the buzzing of a swarm of bees. It is too much to expect of either bears or woodpeckers that they should be versed in the ways of modern science. (*Notes from the Leyden Museum*, October 1890, p. 209.)

ALGÆ LIVING IN THE SHELLS OF MOLLUSKS.—For a long time back zoologists have, in a more or less desultory and unsatisfactory manner, made known to us the occurrence, in the hard parts of both living and extinct animals, of sundry ramifying canals, which have been described as the work of vegetable parasitic forms. These forms have been found in shells, corals, sponges, in fish-scales, and, indeed, the literature of the subject is quite a large one. Until the other day, however, there was but little progress made in our knowledge of the life-history of these parasitic plants, but the researches of Reinsch (*Bot. Zeit.*, 1879), and especially of Lagerheim (*Oefver. af K. Vet. Akad. Forhand.*, 1885), marked a new era in their investigation. A memoir, recently published in the Report of the Botanical Congress held in Paris last year, from the pens of MM. Ed. Bornet and Ch. Flahault, reduces the whole subject to order, describes the method of investigation, and a number of new genera and species. As most of these minute plants grow within the calcareous shells of Mollusca, it is not possible to study their morphology, unless by decalcifying these structures; this is effected by placing them in a sufficient quantity of Perenyi's fluid, consisting of four volumes of a 10 per cent. solution of nitric acid, three of alcohol, and three of a 5 per cent. solution of chromic acid, which fluid, while it dissolves the carbonate of lime, fixes the protoplasm, and leaves it and the other cell-contents (after a good washing) in a fit state for the use of reagents or staining. The same general features seem to attend the gradual perforating of the shell-structure by these parasites. At first they penetrate just under the outer epidermis of the shell, then speedily they make further advances, until in time the greater quantity of the hard structures disappear. This will account for the gradual extinction of dead shells in tranquil bays, where they are not subject to being ground into powder by the force of the waves. In addition to marine shells, instances of the occurrence of these forms in fresh-water shells are given, and they would also seem occasionally to lead an independent existence on calcareous rocks. Of the Chlorosporeæ, the most important is *Gomontia polyrhiza*, briefly described by Bornet and Flahault in Morot's *Journal of Botany* for May 1888, but here fully described and illustrated. This plant has a minute thallus, consisting of ramifying filaments, certain cells of which become altered into sporanges, and become detached; from these issue biciliated zoospores and immobile spores (the aplanospores of Wille). The germination of these spores seems to differ; the aplanospores increase in volume, emit one or more rhizoids, and soon present an appearance resembling that of a sporangium, but smaller. Whether the zoospores conjugate or not has not yet been observed—the difficulties in the way of observation are great—but they soon give origin to filamentous growth of a bright green colour. The other species described are *Siphonocladus voluticola*, *Zygomitus reticulatus*, and *Ostreobium queketti*. Among the Phycochromaceæ are enumerated *Mastigocoleus testarum* (Lagerheim), *Plectonema terebrans*, *Phormidium incrustatum*, and *Hyella cæspitosa*—this last a very interesting species; its thallus has a great resemblance to that of the Sirosiphoniaceæ, but in reality it belongs to the Chamæsiphoniaceæ, and it has two modes of propagation—one by the ordinary dissociation of vegetative cells, and the other by the formation of spore-like bodies resulting from the division of the contents of certain cells into a great number of minute cellular spheroids, after the manner in Dermocarpa, these cells being either terminal or intercalary. Two fungoid forms are described and figured: *Ostracoblabe implexa*, for the form regarded as *Achlya ferax* by Duncan, and *Lithopythium gangliforme*. This memoir seems to open a new field for research. Without doubt many new facts, as well as new species, await the patient labours of our botanists among these shell-frequenting species, and the way is made plain for them in this memoir. (*Bull. Soc. Bot. de France*, tome xxxvi., 1890.)

THE AUSTRALIAN ABORIGINES.

IN the latest number of the Journal and Proceedings of the Royal Society of New South Wales (vol. xxiii. part 2) there are two remarkably interesting articles on the Australian aborigines. One of them is by the Rev. John Mathew, Coburg, Victoria; the other by Mr. Edward Stephens, Bangor, Tasmania. It may be worth while to give a general idea of the contents of both papers.

Of the two, that by Mr. Mathew is by far the more elaborate. It represents the results of observation and study which have evidently been carried on for many years. A considerable part of it is devoted to the question, Who are the Australian aborigines? and about this he has much to say that must command the attention of ethnologists. He holds that the continent was first occupied by a homogeneous people, a branch of the Papuan family, and closely related to the Negroes. These settlers came from the north, but whether from New Guinea or any other island of the Eastern Archipelago we have no means of knowing, because at the time of their arrival the islands to the north were probably all inhabited by people of the same blood. Mr. Mathew thinks that these first-comers, the veritable Australian aborigines, occupied all the continent; and, having spread right across to the southern shores, crossed what is now Bass's Strait, which may at that distant date have been dry land, their migration terminating in Tasmania. According to this view, the now extinct Tasmanians were a survival of the primitive Australian race; and Mr. Mathew is at great pains to mass the evidence in favour of this theory.

One of the strongest arguments against the hypothesis is that the Tasmanians differed in appearance from their neighbours across the Strait. By a careful comparison of various accounts of both races, one of which is well known to him, he has convinced himself that the physiological differences narrow down to these: that, as compared with the natives of the continent, the islanders were on the average of shorter stature, of much darker complexion, and had hair of very different quality. These differences, he thinks, are to be explained by the fact that the Australian aborigines were greatly modified by fresh settlers, whereas the Tasmanians, being separated from other races, retained their primitive characteristics. There are now various physical types in Australia, but the Papuan type has not been effaced. Mr. Mathew cites various authorities to show that there is a decided Papuan fringe on the south-eastern and western coasts, with a departure from it landwards and in the north. The hooked nose is a feature common to Papuans, Australians, and Tasmanians.

Having discussed the argument from mythology and tradition, Mr. Mathew goes on to consider the argument from implements. The Tasmanians, as warriors, were much less skilfully equipped than most Australian tribes. They possessed, for example, neither the shield nor the boomerang, nor were their weapons ornamented. But in Australia there is a people at an equally low stage; and, with regard to those who are more advanced, Mr. Mathew suggests that the arts they possess may have reached Australia after the departure of the tribes who peopled Tasmania. His conclusion, after a survey of all accessible facts, is that the arms of the Tasmanians were of the same kind as those of the lowest of the Australians; and it is, he maintains, anything but illogical to infer that the "autochthonous" Australians once used exactly the same weapons and implements as those of the islanders. By circumstances which affected only the continent, the arms and implements there were almost universally improved. The author further strengthens his case by linguistic evidence, and by reference to customs which were common to Tasmania and the whole or part of Australia.

Having thus set forth his ideas as to the earliest inhabitants of Australia, he proceeds to disentangle and identify the other elements which go to constitute the Australian race as it is now. Upon the original Papuan stock of Australia there must have been grafted a very strong scion from another and in some respects very different stem, and the union must have been effected in the remote past, the stock from which the graft came having since then altered by progressive development almost beyond identification. The new element Mr. Mathew believes to have been the Dravidian. "Although," he says, "the Australians are still in a state of savagery, and the Dravidians of India have been for many ages a people civilized in a great measure and possessed of a literature, the two peoples are affiliated by deeply-marked characteristics in their social system and by sure affinities in language." A reference to the boomerang, which is found in India as well as in Australia, is one of the means by which he endeavours to establish this connection. "We search the Malay and Papuan armouries in vain for any trace of it, and are therefore obliged to credit some other race with its introduction to Australia, unless we unnecessarily assume that it was invented here independently. The boomerang is used in Africa about the upper course of the Nile, but we need not travel so far for it across barriers that might be termed impassable, when it is obtainable so much nearer, and in a plaee from which a highway has led thither almost to Australia's shores. If the framework of society, and those terms which are almost as close to a man as his own name, have both been introduced from India or its neighbourhood, it requires no stretch of imagination to suppose that the boomerang came along with them."

Universal and strong as the Dravidian influence is, it is not sufficient, Mr. Mathew thinks, to account for the great divergence of the Australians from the pure Papuans in physical features and language. He maintains, however, that the phenomena can be explained by the introduction of a Malay element. Mr. Curr is of opinion that the visits of the Malays are only of recent date, and quotes the statement of a Malay, who, in 1803, professed to have been one of the first of his countrymen to visit Australia. According to Mr. Mathew, the evidence of this Malay, whose historical knowledge must have been very limited, is overborne by the physique of the people, in the north especially, but elsewhere as well; by the naturalization of a number of important Malay words, such as the term for "teeth," a change which mere visitors could not effect; and, further, by faces of the Malay type and pure Malay words appearing in localities far removed from casual intercourse, as, for instance, in the extreme east and west. The admixture of Malay blood is supposed to account for the difficulty "that a race such as the Australian, with a Papuan basis, should have the hair straight or wavy, and not woolly. One even cross of a woolly-haired with a straight-haired race would hardly have transmitted such straightness of hair to posterity; but if after a first cross, the fresh invasions, though only in scant filtrations, were of straight-haired people, the effect of the mingling of two straight-haired races with one the hair of which was woolly, would surely be to make the spirals uncurl."

In so far as the succession and distribution or commingling of different races are concerned, Mr. Mathew suggests that the peopling of Australia may be compared with that of Great Britain. Taking the word "Celtic" in the widest sense, he says:—"The Celtic element in Britain is represented by the Papuan in Australia, the Saxon by the Dravidian, the Norman by the Malay. In both cases, population has poured in mainly on one side, the earliest settlers gradually retiring to the further shore. The second race takes entire possession of the centre, shedding the indigenes to either side. Wales and Cornwall might correspond to Victoria, the Isle of Man to Tasmania, not in relative position to the mainland, but in isolation and racial purity, and the Highlands of Scotland would represent Western Australia. In each case, from the first two races the bulk of the people is sprung, and the vocabulary and grammar are inherited; while the third race, sprinkled here and there over the land, has left the slightest lingual traces of its presence."

Dealing with the physical appearance of the natives, Mr. Mathew shows that it is subject to considerable variation, not only in different localities, but even in the same community, and this as regards stature, muscular development, cast of feature, and other particulars. In his opinion the Australians exhibit powers of mind "anything but despicable." In schools it has often been observed that aboriginal children learn quite as easily and rapidly as children of European parents. For three consecutive years the aboriginal school at Ramahyuck, in Victoria, stood the highest of all the State schools of the colony in examination results, obtaining 100 per cent. of marks. But the limit of the native's range of mental development is soon reached; and he has "an inherent aversion to application." He has a strong propensity to mimicry, and "it is astonishing how easily and completely young blacks, not cut off from intercourse with their relatives, but living and working constantly among the whites, fall into European modes of thought." They are not wantonly untruthful, or deficient in courage, or excessively selfish, and they are "by no means lacking in natural affection." But they have no stability, so that their moral qualities are prone to operate capriciously. An almost universal feature of the aboriginal character is "gaiety of heart"; and Mr. Mathew believes this to be a Papuan inheritance. The black is a very vain man, and it is "perhaps as much owing to his vanity or his fondness for praise as to any other motive that he has been got to work at all."

The paper includes instructive paragraphs on dwellings, clothing, implements, food; government, laws, institutions; marriage, man-making, mutilations, burial customs; art, corroborees, sorceries, superstitions; and the Australian languages. Speaking of the magicians called "doctors," corresponding to the medicine-men and rain-makers of other barbarous peoples, Mr. Mathew says:—"The power of the doctor is only circumscribed by the range of his fancy. He communes with spirits, takes aërial flights at pleasure, kills or cures, is invulnerable and invisible at will, and controls the elements. I remember a little black boy, when angry, threatening me with getting his father to set the thunder and lightning agoing. The same boy told me seriously that on the occasion of a raid being made upon the blacks' camp by the native police, one of his fathers—a doctor—lifted him and pitched him a mile or two into the scrub, and vanishing underground himself, reappeared at the spot where the boy alighted." The Australians have "an apprehension of ghosts rather than a belief in them." In the tribe with which Mr. Mathew is best acquainted, they had a term for ghosts, and thought that departed spirits were sometimes to be seen among the foliage; but "individual men would tell you upon inquiry that they believed that death was the last of them." A ghost was called a "shadow," and the conception of its existence was "shadowy" like itself. "The Kabi tribe deified the rainbow—a superstition apparently confined to this people. He lived in unfathomable water-holes in the mountains, and when visible was in the act of passing from one haunt to another. He was accredited with exchanging children, after the fashion of the European fays."

Of Mr. Stephens's paper we have not space to say much. It is of special interest, because it is nearly half a century since he landed, a lad with his parents, in the infant colony of South Australia; and since that time he has had many opportunities of observing the natives. He does not at all agree with those who think that the Australians are "a naturally degraded race." Those who talk in this way, he says, either do not speak from experience, or judge the aborigines by what "they have become when the abuse of intoxicants and contact with the most wicked of the white race have begun their deadly work." "As a rule, to which there are no exceptions, if a tribe of blacks is found away from the white settlement, the more vicious of the white men are most anxious to make the acquaintance of the natives, and that, too, solely for purposes of immorality. The native women have hearts to break, and the native men outraged honour to vindicate, and these have ever been the chief factors in the so-called atrocities of the aborigines of Australia. I saw the natives, and was much with them, before these dreadful immoralities were well known. I saw them, and was often with them, when the old died off, and the race no longer propagated itself; and I say fearlessly that nearly all their evils they owed to the white man's immorality and to the white man's drink."

Mr. Stephens has a very favourable opinion of the capacity of the Australians for mental improvement. A full-blooded native, called Cottrel, whom he knew, was "an agreeable companion, interesting in conversation, full of anecdote and adventure." He married a white woman, and settled comfortably, near the

Bremer, on land given to him by the South Australian Government. "To see him track, or smell the tracks of his own bullocks that had gone astray with a number of others, was a sight long to be remembered"; and he never failed to find them.

An odd and significant incident which occurred long ago is described by Mr. Stephens. Some men of the eastern tribes called at his father's house on their way inland. "There being only my mother and myself at home, and the nearest neighbour some distance away, the men became very bold and bodily entered the house. We had a nice lively little magpie at the time, which we had tamed and taught to say a few words, and to whistle 'There's nae luck about the house,' &c. The magpie hid himself under the sofa, and, singularly incredible as it may appear, it, in a rich, full, clear tone, whistled the tune "There's nae luck,' &c. The natives were strangely silent in a moment. In less time than it takes to pen the words, little mag was out from his hiding-place, biting the naked toes of the savages here, there, and everywhere, and talking at a tremendous rate. They all looked like a lot of scared demons, and madly rushed for the door, as if the old general himself were after them. The door was instantly closed and bolted. The blackfellows never returned, and never knew but that the words came from an avenging spirit, and that they had had a very narrow escape."

GARDEN SCHOLARSHIPS.

IN accordance with the intention of its honoured founder, the Trustees of the Missouri Botanical Garden propose to provide adequate theoretical and practical instruction for young men desirous of becoming gardeners. It is not intended at present that many persons shall be trained at the same time, nor that the instruction so planned shall duplicate the excellent courses in agriculture now offered by the numerous State Colleges of the country, but that it shall be quite distinct and limited to what is thought to be necessary for training practical gardeners.

To this end, the following resolution was adopted by the trustees, at a meeting held on November 19, 1889:—

"*Resolved*, That there be established the number of six scholarships for garden pupils of the Missouri Botanical Garden, to be available on and after April 1, 1890, such scholarships to be awarded by the Director of the Garden on the results of competitive examination, except as hereinafter provided, to young men between the ages of 14 and 20 years, of good character, and possessing at least a good elementary English education; each scholarship to grant such privileges and be subject to such conditions as are provided below or may subsequently be provided by the Trustees of the Garden.

"Until otherwise ordered, two such scholarships shall be reserved for candidates to be named by the State Horticultural Society of Missouri, and the Florists' Club of St. Louis, respectively; provided, that such candidates shall be given scholarships only after passing satisfactory preliminary examinations, and shall be subject after appointment to all tests and regulations prescribed for other candidates and pupils, and that if the names of such candidates are not presented by the societies designated, within sixty days after such action is requested by the Director, the vacancies may be filled by him on competitive examination, as in other cases.

"Each scholarship so conferred may be held by the original recipient for a period not exceeding six years, subject to the following conditions:—

"Each garden pupil shall be required to lead a strictly upright and moral life, and shall be courteous and willing in the performance of all duties prescribed for him. He shall devote his entire time and energy to the labour and studies prescribed for him, except that from time to time he may be granted leave of absence to visit his home or for other good reason, at the discretion of the Director, provided that the aggregate of such absences in any calendar year shall not exceed thirty days. He shall also show such ability in his work and studies as to satisfy the Director that it is advantageous for the scholarship to be held by him; and from time to time he may be subject to both theoretical and practical examinations, or may be given special tasks calculated to test his knowledge or resources. Failure to meet the requirements in any one of these respects, making due allowance for extenuating circumstances, shall forfeit all claim on any scholarship, which may then be awarded to another person in the prescribed manner.

"Garden pupils, appointed as above indicated, shall be regarded as apprentices in the Botanical Garden, and as such shall be required to work in it under the direction of the head gardener, performing the duties of garden hands. They shall be successively advanced from simpler to more responsible tasks; and in such order as may seem best shall be transferred from one department of the Garden to another, until they shall have become thoroughly familiar with the work of all.

"To the end that Garden pupils shall be repaid for their services to the Garden, and that the absence of pecuniary means need not deter any young man from obtaining such training as is contemplated, each regularly appointed garden pupil holding a scholarship shall be entitled to the following wages, payable in equal instalments at the end of each fortnight: for the first year 200 dollars; for the second year, 250 dollars; and for each year after the second, 300 dollars; together with plain but comfortable lodgings convenient to the Garden.

"In order that they may have opportunity to become instructed in the theoretical part of their profession, and in subjects connected therewith, such pupils shall not be required to do manual work in the Garden for more than five hours per day after the first year, devoting the remainder of their time to the study of horticulture, forestry, botany, and entomology, under the direction of the Director of the Garden; and they shall for this purpose be granted free tuition in the School of Botany of Washington University. They shall also receive practical instruction in surveying and book-keeping, so far as a knowledge of these subjects is held to be necessary for a practical gardener charged with the management of an estate of moderate proportions.

"At the expiration of six years, the holder of a scholarship, who is recommended as practically proficient, shall be entitled to examination by the Garden Committee, in the subjects prescribed for study, and on passing such examination to the satisfaction of the Committee and Director, he shall receive a certificate of proficiency in the theory and practice of gardening signed by the Chairman of the Garden Committee and the Director of the Garden. In exceptional cases, candidates may be admitted to examination at the end of the fifth year, when this shall be deemed advisable by the Garden Committee, and on passing such examination satisfactorily, shall be entitled to a statement to that effect from the Director, and to the regular certificate on the subsequent completion of a year's work to the satisfaction of their employers."

All applicants for scholarships, whether named by the societies indicated above or not, will be examined in the following subjects so far as they are taught in the upper classes of grammar schools: English grammar, reading, writing, and spelling; arithmetic; and geography. If the number of candidates for scholarships exceeds the number of scholarships to be awarded at any time, all candidates except those named by the societies indicated will be required to pass a further competitive examination, which will cover history of the United States, English literature, algebra, German, the elements of botany, zoology, and physiology, and such other subjects as may from time to time be prescribed. It is not intended to make the passing of examinations in these last-named branches a requirement for the award of scholarships, but merely in this way to obtain a means of selecting the most deserving and able candidates when it is necessary to reject some. Hence, the Director will always use his discretion as to the importance to be attached to greater or less proficiency in any of the subjects covered by competitive examinations, as well as to the other qualifications of candidates admitted to such examinations.

Under the above provisions, the following announcement is made:—

Two scholarships will be awarded by the Director of the Garden, prior to April 1 next. In case both are not then awarded, the remainder will not be awarded until the corresponding period of the following year, and vacancies which may subsequently arise will be filled annually, after published announcement.

Applications for scholarships, to receive consideration, must be in the hands of the Director not later than March 1. The preliminary examination for all candidates will be held on Tuesday, March 3, at the Shaw School of Botany, 1724 Washington Avenue, St. Louis, between 10 a.m. and 5 p.m. If the number of applicants exceeds two, competitive examinations, based on the subjects indicated above, will be held at the same place on Friday and Saturday, March 6 and 7.

Candidates who live at places remote from St. Louis, and who wish to be spared the expense of coming to the city for examination, may send, with their application, the name and address of the principal of the nearest high school, or of some approved private school, in case he is willing to take charge of such examination for them; but all applications of this character must be in the hands of the Director not later than the middle of February. If the examiner is approved, papers will be sent to him before the date set for the examination, and on the payment of a fee of 2 dollars to him, the candidate may write on them in his presence. If competitive examinations are also required, the same examiner will receive the papers for them in time to submit them to the candidate on the date set for similar examinations in St. Louis, on receipt of an additional fee of 3 dollars as a partial payment for his time in conducting the examination. The papers written on such examinations will be forwarded by the examiner to the Director, who will read them in connection with those written in St. Louis, before making any awards.

Successful candidates will be started in their duties as garden pupils on Tuesday, March 31, at the Botanical Garden. They will be lodged in comfortable rooms in a spacious dwelling adjoining the Garden under the charge of the head gardener, or some other competent person. It is not the intention of the Trustees to furnish table board, but good board can be obtained in the lodging-house or elsewhere at the usual cost. The lodging-house includes a reading-room supplied with the more valuable horticultural and agricultural papers, and also with a small but standard collection of books on the same subjects, which the pupils have free use of. So far as possible, the surroundings of pupils are made home-like, and, without assuming any responsibility for their behaviour, an effort is made to subject them to influences calculated to insure for them gentlemanly manners and habits of industry and investigation.

During the first year of their scholarship, garden pupils will work at the practical duties of the Garden nine or ten hours daily, according to the season, the same as regular *employés* of the Garden, and will also be expected to read the notes and articles referring to the subject of their work in one or more good journals.

In the second year, in addition to five hours' daily work of the same sort, they will be given instruction and will be required to do thorough reading in vegetable gardening, flower gardening, small-fruit culture, and orchard culture, besides keeping the run of the current papers.

In the third year, in addition to five hours of daily labour, they will be instructed and given reading in forestry, elementary botany, landscape gardening, and the rudiments of surveying and draining, and will be required to take charge of clipping or indexing some department of the current gardening papers for the benefit of all.

In the fourth year, besides the customary work, they will study the botany of weeds, garden vegetables, and fruits, in addition to assisting in the necessary indexing or clipping of papers, &c., and will be taught simple book-keeping, and the legal forms for leases, deeds, &c.

The course for the fifth year, in addition to the customary work, will include the study of vegetable physiology, economic entomology, and fungi, especially those which cause diseases of cultivated plants; and each pupil will be expected to keep a simple set of accounts pertaining to some department of the Garden.

In the sixth year, in addition to the manual work, pupils will study the botany of garden and green-house plants, of ferns, and of trees in their winter condition, besides the theoretical part of special gardening, connected with some branch of the work that they are charged with in the Garden.

From time to time changes in this course will be made, as hey shall appear to be desirable, and the effort will be made to give the best theoretical instruction possible in the various subjects prescribed; but it is not intended to make botanists or other scientific specialists of garden pupils, but, on the contrary, practical gardeners.

Applications for scholarships, and any inquiries regarding them, are to be addressed as below, on or before the dates mentioned above. If requested, blanks will be mailed to persons who contemplate making application.

WILLIAM TRELEASE,
Director of the Missouri Botanical Garden,
St. Louis, Mo.

WASHINGTON OBSERVATIONS, APPENDIX I.

THIS volume consists of reports, to the Superintendent, of the Transactions of the International Astrophotographic Congress, and of "A Visit to certain European Observatories and other Institutions," by Albert G. Winterhalter.

In the first report will be found a good detailed account of the most important points that have been discussed in order to obtain the best and most accurate methods by which a chart of the heavens may be made. Among the resolutions that were passed at this Congress, the following may be mentioned:—Refractors shall be used exclusively, the object-glasses of which shall have apertures of 33 centimetres and focal lengths of about 3·43 metres. The aplanatism and achromatism of these glasses shall be calculated for the wave-lengths near the Fraunhofer line G, by which means use may be made of the maximum of sensitiveness of the photographic plates. All the plates will be prepared from a single formula, and as regards their sensitiveness a permanent control will be instituted. In order to eliminate defects in the plates, two series of photographs of the whole sky will be made, and so arranged that stars on the edges of one will be more or less central on the other. In addition to the above-mentioned series of plates, another will be taken with shorter exposures, so as to obtain greater precision in the micrometric measurement of the fundamental stars, and to make possible the formation of a catalogue. The author, in his general conclusions at the end of this report, points out the necessity for a mutual dependence and relation of all workers in astronomy, and he adds, "The necessity becomes urgent in the light of the late development and the multiplying branches of that science. Had there been no practical results of the international reunion at Paris, there would still have remained much good derived from personal acquaintance and discussion."

The second part of the work forms a most valuable record of the instruments that are employed in most of the chief Observatories of to-day. The author made the visits in obedience to orders of the Department and of the Superintendent that were issued to him, all of which he has appended in the latter end of Part IV. To give an account of the various Observatories described in this volume, or even to summarize the information recorded, would occupy too much space, so that we will restrict ourselves to the visit paid to England, and make some brief extracts relating to the Observatories mentioned.

Of course, the first Observatory visited was that of Greenwich, and the author does not give such a detailed account of it as he does of many others, as "no observatory is more intimately known to Americans. This is largely due to the thoroughness with which the parts have been described from time to time, and to the frequency with which the establishment has been referred to as a model in one or the other particular." At any rate, he gives a good description of most of the chief instruments employed, with details of their construction; he also paid great attention to the various styles of domes employed, and the means adopted for rotating them. The photoheliograph is described, also the magnetical and meteorological instruments, and a brief account is given of the chronometer, time signals, clocks, and chronographs.

The next Observatories visited were those of Kew, Huggins's, and Common's; during the author's stay at the last-named Observatory the 5-foot mirror was in progress of rough polish. He also briefly states the means that were going to be adopted for floating the axis, the tube of which would measure 8 feet in diameter, so that its ends would then only have to be confined to the extremities of the tank by pins.

The visits of the author not being strictly confined to Observatories, he went over the workshops of Troughton and Simms, that are situated at Charlton, in which he saw instruments of all kinds in course of construction. As a typical example of the work turned out he takes the transit-circle with an object-glass of 8 inches and a focal length of 9 feet, an illustration of which is given.

The last English Observatories visited were those of Oxford and Cambridge, and after some short historical notes, the various instruments in each are described in detail.

Part III. consists of reports on sundry astronomical and nautical constructions and processes, and amongst the subjects treated may be mentioned the following: the construction of the great dome at Nice, M. Bigourdan's apparatus for determining the personal equation in double-star measurements, various forms of artificial horizons, a new level-trier, public time-service, and the equatorial coudé.

In Part IV. the author relates a few very general conclusions that he has arrived at after his series of visits, some of which we will state quite briefly. Each prominent instrument should have its own building; dwellings for observers should be on the premises; good workshops should be provided, so that repairs may be done on the spot; and electricity should be used throughout. Copies of the orders from the Navy Department follow next in order; and the volume terminates with a list of books, photographs, &c., that were bought at the various places visited.

The work as a whole supplies the reader with an excellent and trustworthy description of many of the chief Observatories of the present day; it may be stated, however, that the author has deemed it necessary to omit a large amount of information on methods, instruments, &c., his reason for so doing being that it will be found in other publications.

The illustrations throughout add greatly to the value of the book, and the American Government ought to be congratulated on the result of the work.

FIELD EXPERIMENTS AT ROTHAMSTED.[1]

THESE memoranda are issued yearly, in order to bring the results of the field experiments up to the present time. The matter is closely condensed, most of the information being in the form of schedules and tables. The results include observations and experiments upon rainfall, drainage, composition of drainage water, disposal of rainfall through percolation and evaporation, as well as upon the effects of artificial manures on various crops, most of which have been grown upon the same land, under strictly regulated conditions, for forty years. To those who are accustomed to follow the results obtained at Rothamsted, there is nothing novel in those portions of the memoranda, as they merely contain the account of a work with which the agricultural public is familiar. No one not already aware of the elaborate nature of the Rothamsted experiments can take up these memoranda without being struck with the vast amount of labour, patience, expenditure, and ability disclosed. Agriculturists will probably be disposed to confine their attention to the effects of fertilizers upon certain crops, but after perusing this interesting document we come to the conclusion that the Rothamsted observations reach much further in their significance than the limits of agricultural practice. They must assist in the solution of physiological questions involving both animals and vegetables, and physical questions relating to the gradual changes wrought upon the surface of the earth through rainfall and atmospheric action. The Rothamsted results, carefully tabulated year by year, contain a mass of data from which important conclusions may be drawn. Among these data we note—(1) Observations upon the determination of nitrogen as ammonia, as nitric acid, and as organic nitrogen, and also some other constituents, in many samples both of the rain and of the various drainage waters collected at Rothamsted. It is only by such observations that any idea can be formed as to the sources of the nitrogen of growing plants. We have here a means for estimating both the amount of nitrogen brought down in rain and wasted through drainage—two factors which must be kept in view when the relations of plants to combined nitrogen at present existing in the soil are to be investigated. (2) Observations on the difference in the character and amount of the constituents assimilated by plants of different botanical relationships, under equal external conditions, or by the same description of plants under varying conditions. (3) Observations on the character and range of the roots of different plants, and on their relative development of stem, leaf, &c. (4) Observations on the composition of the entire plant, and various parts of the same plants, at different stages of growth.

One of the most important subjects, which has acquired fresh interest at the present time, is that of the assimilation of free nitrogen by growing plants. In treating of this deeply interesting question Sir John Lawes says:—"In recent years this question has assumed quite a new aspect. It now is, whether the free nitrogen of the atmosphere is brought into combination under the influence of micro-organisms or other low forms, either within the soil or in symbiosis with a higher plant, thus serving indirectly as a source of nitrogen to plants of a higher order. Considering that the results of Hellriegel and Wilfarth on this point were, if confirmed, of great significance and importance, . . . a preliminary series (of experiments) was undertaken in 1888, a more extended one was conducted in 1889, and the subject is being further investigated in the present year. The results so far obtained show that, when a soil growing leguminous plants is infected with appropriate organisms, there is a development of the so-called leguminous nodules on the roots of the plants, and, coincidently, increased growth and gain of nitrogen. These results were obtained after adding to a sterilized sandy soil growing leguminous plants a small quantity of the watery extract of a soil containing the appropriate organisms. There is no evidence that the leguminous plant itself assimilates free nitrogen; the supposition is rather that the gain is due to the fixation of nitrogen in the growth of the lower organisms in the root nodules, the nitrogenous compounds so produced being taken up and utilized by the leguminous plants. It would seem, therefore, that in the growth of leguminous plants, such as clover, vetches, peas, beans, lucerne, &c., at any rate some of the large amount of nitrogen which they contain may be due to atmospheric nitrogen brought into combination by the agency of lower organisms." No hint is given as to the identity of the "lower organism" so frequently mentioned, but there is reason to think that it is a fungus belonging to the class *Ustilaginæ*, which exists in and is the cause of the tubercles, or root nodules, found upon the root fibres of leguminous plants.

The bulk of the memorandum is occupied with the continuation and re-editing up to date of the results obtained at Rothamsted by the application of fertilizers. The matter is important, but as it takes the form of an annual report in which the latest results are added to and incorporated with those of previous years, already noticed by us in due course, we must refrain at the present time from more lengthy notice. Sir John Lawes has always been a stout advocate of the view that the source of nitrogen in plants was to be looked for *in the soil* and not in the air. It is, therefore, an interesting fact, as between him and the believers in the assimilation of atmospheric free nitrogen, that the micro-organisms in question seem to offer a *modus vivendi*, or means of reconciliation, between two hitherto conflicting doctrines.

[1] "Memoranda of Field Experiments at Rothamsted, Herts, conducted by Sir John Lawes, Bart." 1890.

SCIENTIFIC SERIALS.

IN the *American Meteorological Journal* for November, Prof. W. Ferrel replies to the attacks made by Prof. Hazen on Espy's experiments on storm generation. He points out that this theory does not rest upon the experiments of Espy alone, but on those of Regnault, Clausius, Sir W. Thomson, and others, all of which were finally embraced in a convenient formula by Dr. Hann, and adopted by himself (*Meteor. Zeitsch.*, 1874, and Smithsonian Report, 1877). M. H. Faye continues his articles on the "Accessory Phenomena of Cyclones." This number also contains a summary of a report by Mr. W. Ogilvie on his exploration of the Canadian Yukon, and the region between it and the Mackenzie, in 1887 and 1888, embracing some portions of country never before visited by a white man. He wintered in 1887 in lat. 64° 61′, long. 140° 54′. The maximum pressure in January reached 30·3 inches or 0·3 inch higher than the most trustworthy maximum isobars for that region. The mean minimum temperature in December was $-33°·6$, and the absolute minimum in the same month $-55°·1$. The mean temperature is not given. Drifting ice in the river commenced on October 21, the ice set on November 15, and on February 3 the thickness amounted to 48 inches. From the station on the Yukon to one on the Porcupine, lat. 65° 43′ long., 139° 43′, the following meteorological notes are given: lowest temperature in April, $-37°$. The last time a minus reading was recorded was May 5, $-1°·8$. Highest temperature in April, 40° on 30th; the highest in May, 55° on 7th. The report contains a series of notes on the opening and closing of the Mackenzie, on the duration of sunlight, and on the climate and capabilities of that region. Green clouds, a phenomenon apparently rare, were observed on the mornings of February 19 and 29 just before sunrise; at the same time there was a slight fall of minute ice-crystals.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 11.—"On Ellipsoidal Harmonics." By W. D. Niven, F.R.S.

In this paper some of the properties of these functions are obtained from a discussion of their expressions in Cartesian co-ordinates.

If Θ_r denote

$$\frac{x^2}{a^2+\theta_r}+\frac{y^2}{b^2+\theta_r}+\frac{z^2}{c^2+\theta_r}-1,$$

the general expression for an ellipsoidal harmonic is given by

$$G = (1, x, y, z, yz, zx, xy, xyz)\Theta_1 \ldots \Theta_n,$$

where any of the quantities inside the brackets is the multiplier of the product of Θ's outside, provided n equations of the form

$$\frac{p}{a^2+\theta_1}+\frac{q}{b^2+\theta_1}+\frac{r}{c^2+\theta_1}+\frac{4}{\theta_1-\theta_2}+\ldots+\frac{4}{\theta_1-\theta_n}=0$$

are satisfied, p, q, r being respectively 3 or 1, according as G does or does not contain x, y, z as factors.

For the same values of θ, another function satisfies Laplace's equation, given by

$$H = (1, x, y, z, yz, zx, xy, xyz)K_1 \ldots K_n,$$

where

$$K_r - 1 = \Theta_r.$$

The functions (H) are spherical harmonics, and several properties of the functions (G) depend upon those of (H).

The functions (G) are applicable to the interior of the ellipsoid. Those pertaining to the exterior, as is well known, are of the form GI, where I is a certain integral depending on the quantities θ pertaining to G.

If G and H are corresponding functions of the nth degree according to the above definitions, then

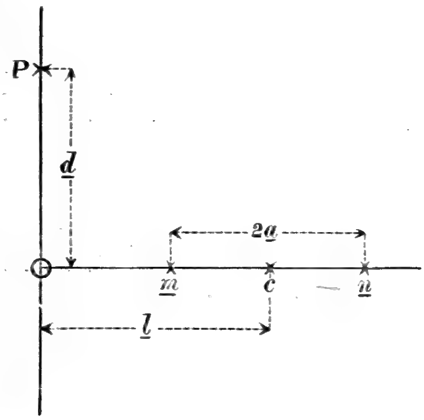
$$GI = (-1)^n \frac{1}{2^n n!} H\left(\frac{d}{dx}, \frac{d}{dy}, \frac{d}{dz}\right)V_n,$$

where V_n is the potential at xyz due to an ellipsoid whose density at any internal point f, g, h is

$$n\left(1-\frac{f^2}{a^2}-\frac{g^2}{b^2}-\frac{h^2}{c^2}\right)^{n-1}.$$

The remainder of the paper is occupied with the reduction and application of these results to ellipsoids of revolution.

Physical Society, November 28.—Prof. W. E. Ayrton, F.R.S., President, in the chair.—The following communications were made:—Additional notes on secondary batteries, by Dr. J. H. Gladstone, F.R.S., and Mr. W. Hibbert. After referring to the debatable points as to what compounds are formed and decomposed in the working of such batteries, the authors give the results of their examination of the red substance formed by the action of dilute sulphuric acid on minium, and which Dr. Frankland believes to be a compound having the formula $Pb_3S_2O_{10}$. The ultimate analysis showed 72 per cent. of lead. A portion of the substance was treated with a 3 per cent. solution of ammonium acetate to dissolve out any normal sulphate that might be present; this left a residue much darker in colour than the original substance, and containing 82 per cent. of lead. PbO_2 contains 86·6 per cent. of lead. The colourless solution yielded a ratio of Pb to SO_4, varying from 2·0 to 2·15; pure $PbSO_4$ requires a ratio of 2·16, and Frankland's compound 3·23. From these results the authors conclude that the portion dissolved was not a basic sulphate, and that the evidence tells against the original substance being a chemical compound. The authors have also continued their comparative experiments on the action of spongy lead on dilute sulphuric acid, either pure, or containing a small quantity of sulphate of soda. After the experiments had gone on for five months, the residues were analyzed; that from the pure acid showed 82 per cent. of lead sulphate and 18 per cent. of metallic lead, whilst that mixed with sodium sulphate gave 89 per cent. of lead sulphate and 11 per cent. of lead. They therefore conclude that although the action of acid on lead is initially diminished by the presence of sodium sulphate, the final result is rather the other way. Mr. G. H. Robertson, who had used ammonium acetate to analyze plugs from storage cells, said he had arrived at results much the same as those stated by the authors. Mr. Swinburne said Dr. Frankland was absent, but, without agreeing with him, he would suggest that Dr. Frankland might say that ammonium acetate decomposed the subsalt $Pb_3S_2O_{10}$, and then dissolved the sulphate $PbSO_4$. The question might be attacked by acting on equal quantities of the substance and the mixture PbO_2, $2PbSO_4$, in a calorimeter with ammonium acetate, to see if the same heat is produced; this would show whether the substance is a mixture or a compound. Dr. S. P. Thompson was glad that the authors allowed a possibility of basic sulphate being formed, for it was well known that an almost irreducible sulphate resulted from leaving a cell nearly discharged; this, he thought, would point to a possible formation of a basic sulphate from PbO and $PbSO_4$. Mr. Swinburne did not see where the PbO came from, except in newly pasted negatives, and he knew of no evidence of an intermediate stage of oxide on the plates. They appear to change directly to sulphate. Dr. Thompson said that a rapid discharge was known to produce basic salts. This, Mr. Swinburne thought due to deficiency of acid near the plates. Peroxide, he said, could not be formed on the negative, without the acid was heterogeneous and gave rise to local currents. Mr. W. Hibbert, referring to Mr. Swinburne's statement, said he had put one plate of spongy lead into strong acid and another into weak, and from this arrangement obtained a fairly large current. As regards the basic sulphate spoken of by Dr. Thompson, he did not think there was much probability of its being formed. Time, he said, had an important influence on a partially discharged cell, and he would not expect to easily reduce the $PbSO_4$ formed by the long-continued action of lead on sulphuric acid. The President inquired whether Mr. Hibbert's argument would apply to a fully charged cell. Mr. Hibbert, in reply, said that in this case the time required to produce sufficient sulphate to be irreducible would be very much longer, for in a partially discharged cell much sulphate was already formed. Dr. Gladstone said he had anticipated that Dr. Frankland would raise the objection referred to by Mr. Swinburne. As far as he was aware, there was no direct evidence either way, but he thought that the suggested decomposition was improbable. If he acted on a mixture of PbO_2 and $PbSO_4$, he would expect to get the results actually obtained. Mixtures, however, were difficult to deal with, and the results not conclusive, for the physical condition of the mixture was not the same as that of the actual products. Referring to Dr. Thompson's remarks, he understood that it was the basic sulphate which he (Dr. Thompson) considered irreducible. Dr. Frankland, however, believed this sulphate more easily reduced than $PbSO_4$. The President remarked that he thought Dr. Frankland had two reasons for his belief in the existence of the basic sulphates. One of these was the difficulty in reducing normal sulphate, whilst the other was based on the rapid fall of E.M.F. at a certain part of the discharge. It was at this point that Dr. Frankland thought the new sulphate formed, and to meet this argument it was necessary to find some other explanation of the rapid fall. In this connection he (the President) inquired whether there was sufficient peroxide formed on the negative plate to account for the drop. On this point Dr. Gladstone could not speak decisively.—An illustration of Ewing's theory of magnetism, by Prof. S. P. Thompson. A number of small "charm" compasses were placed together on a glass plate of an ordinary vertical attachment to a lantern. A large magnet at a distance served to neutralize the earth's field, and a coil enabled a magnetizing force to be applied in the plane of the needles. By this apparatus all the various phenomena exhibited by Ewing's model were beautifully shown on a screen. In the course of his experiments Dr. Thompson had found that when small magnets placed at moderate distances apart were used, it was much more necessary to neutralize the earth's field, in order that they might set themselves according to their mutual attractions, than when larger magnets were employed. A weak field directed the small openly spaced magnets, whereas with larger ones, their mutual actions were much more powerful. This fact may, he thought, throw some light on the molecular groupings in magnetite (loadstone). This substance exists in two forms, viz. one crystalline and the other of a heterogeneous structure. The former variety exhibits no magnetic retentiveness, whilst the latter is decidedly magnetic. As far as he was aware, no sufficient explanation had been given of the non-retentiveness of the crystalline variety. A difference in the molecular distances or groupings might account for the peculiarity. Mr. Boys said it was rather curious that Prof. Rücker had just devised a somewhat similar illustration of Ewing's theory, and he exhibited it at the meeting. It consists of little magnets made of long U-shaped pieces of watch-spring pivoted by glass caps on needle-points; the needle-points are fixed in little disks of lead stuck on a sheet of glass which forms the base of a glass box. An open helix surrounding the box serves to apply magnetic force. Mr. Swinburne called attention to two theoretical points. First as regards susceptibility (which he regarded as a mere ratio and not a property), he said that if particles of iron at a high temperature rotate, as has been supposed, the susceptibility should be negative, and Prof. Ewing had some reason to think that this was the case. The next point concerned the loss of energy when an armature rotates in a strong magnetic field; this, he said, was known to be considerable, whereas if Ewing's theory is correct he would expect little or no loss, for all the little magnets would always put themselves in the direction of the field, and would never pass through positions of unstable equilibrium. The President said he had discussed the question of negative susceptibility some years ago with Dr. Lodge, with reference to the drop in the characteristics of dynamos, but he was not aware that any direct evidence had been obtained. Prof. Perry thought negative susceptibility might be possible in strong fields but not in weak ones. Mr. Swinburne, on the contrary, considered its existence would be more marked in weak fields. Mr. H. Tomlinson said he had tried experimentally whether the susceptibility of nickel, when heated above its critical temperature, was negative, but he had not been able to detect it, although his apparatus was very sensitive.—The solution of a geometrical problem in magnetism, by Thomas H. Blakesley. The problem referred to was the following: Given the two poles of a magnet and a straight line intersecting at right angles, its axis produced, to determine at what point this line is parallel to the field. The question is of scientific interest, because, if the point be found experimentally, the distance between the virtual poles of the magnet can be determined, whilst it is important practically from its bearing on the deviation of ships' compasses in certain cases. The instances in which it would apply are pointed out in the paper. Assuming



the points m and n (see diagram) to be the positions of the virtual poles, and P the required point, it is shown that

$$\frac{m}{(d^2 + m^2)^{\frac{3}{2}}} = \frac{n}{(d^2 + n^2)^{\frac{3}{2}}},$$

where

$$Om = m, \quad On = n, \quad \text{and } OP = d.$$

From this the expression

$$\left(\frac{d^2}{2mn}\right)^3 - \frac{3}{4}\frac{d^2}{2mn} - \frac{1}{4}\frac{m^2 + n^2}{2mn} = 0,$$

is deduced. Now, in hyperbolic trigonometry, we have a formula

$$\cosh^3\theta - \tfrac{3}{4}\cosh\theta - \tfrac{1}{4}\cosh 3\theta = 0,$$

hence making

$$\frac{m^2 + n^2}{2mn} = \cosh 3\theta;$$

we have also

$$\frac{d^2}{2mn} = \cosh\theta.$$

The value of θ can be then found by aid of the tables of hyperbolic sines and cosines compiled by the author, and published recently by the Society. The distance d can thus be determined in terms of m and n. A method of finding the point experimentally is then described, and the distance between the poles ($2a$) shown to be given by the expression

$$\frac{a}{l} = \tanh\frac{3\theta}{2},$$

where

$$\frac{l}{d} = \sqrt{\frac{\cosh 3\theta + 1}{4\cosh\theta}},$$

l being the distance Oc. The latter function can be deduced from the tables already referred to. Experiment shows that the distance between the virtual poles soon approaches the length of the magnet, as d increases. The strength of the field at P is given by the expression

$$\frac{4M}{d^3}\,\frac{\cosh^2\theta}{4\cosh^2\theta - 1}$$

where M is the moment of the magnet. This can be simplified by arranging d and l so that

$$\cosh^2\theta = \frac{5}{4},$$

and then becomes

$$\frac{5}{8}\frac{M}{d^3}.$$

Under these conditions

$$\frac{l}{d} = 0{\cdot}85065,$$

and therefore the angle

$$OCP = 40^\circ\ 23'\ 10''.$$

Entomological Society, December 3.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—Dr. D. Sharp, F.R.S., exhibited specimens of *Papilio polites*, *P. erithonius*, and *Euplœa asela*, received from Mr. J. J. Lister, who had caught them on board ship when near Colombo, in November 1888. Dr. Sharp read a letter from Mr. Lister, in which it was stated that from the ship hundreds of these butterflies were seen flying out to sea against a slight breeze. Many of them, apparently exhausted by a long flight, alighted on the deck of the ship, and large numbers perished in the sea.—Lord Walsingham exhibited a coloured drawing of a variety of *Acherontia atropos*, which had been sent to him by Mons. Henri de la Cuisine, of Dijon. He also exhibited specimens of an entomogenous fungus, apparently belonging to the genus *Torrubia*, growing on pupæ (received from Sir Charles Forbes), which had been collected in Mexico by Mr. H. B. James. Mr. McLachlan, F.R.S., expressed an opinion, in which Mr. C. O. Waterhouse and Mr. G. C. Champion concurred, that the pupæ were those of a species of *Cicada*. Mr. F. D. Godman, F.R.S., said that at the meeting of the Society on October 3, 1888, he had exhibited a larva of a *Cicada* with a similar fungoid growth. —Mr. R. Adkin exhibited male specimens of *Spilosoma mendica*, Clk., bred from ova obtained from a female of the Irish form which had been impregnated by a male of the English form. These specimens were of a dusky white colour, and were intermediate between the English and Irish forms.—Mr. R. W. Lloyd exhibited specimens of *Anisotoma Triepkei*, Schmidt, and *Megacronus inclinans*, Er., collected last August at Loch Alvie by Aviemore.—Mr. Merrifield read a paper entitled, "On the conspicuous changes in the markings and colouring of Lepidoptera caused by subjecting the pupæ to different temperature conditions," in which it was stated that the results of many experiments made on *Selenia illustraria* and *Ennomos autumnaria* tended to prove that both the markings and colouring of the moth were materially affected by the temperature to which the pupa was exposed: the markings, by long-continued exposure before the last active changes; the colouring, chiefly by exposure during these last changes, but before the colouring of the perfect insect began to be visible, a moderately low temperature during this period causing darkness, a high one producing the opposite effect, and two or three days at the right time appearing in some cases sufficient. Dryness or moisture applied during the whole pupal period had little or no effect on either markings or colouring. Mr. Merrifield said he had obtained from summer pupæ of *illustraria* some moths with summer colouring and spring markings, some with spring markings and spring colouring, and some with summer markings, but an approach to spring colouring. These specimens, with enlarged and coloured photographs of them were exhibited. Mr. C. Fenn, who said he did not agree with Mr. Merrifield's conclusions, exhibited a very long and varied series of *Ennomos autumnaria*, all of which, he stated, had been bred at the same temperature. He expressed an opinion that the presence or absence of moisture, rather than differences of temperature, was one of the principal causes of variation. The discussion was continued by Lord Walsingham, Colonel Swinhoe, Mr. Waterhouse, Mr. Jenner-Weir, Captain Elwes, Mr. McLachlan, Mr. Porritt, Dr. Mason, Mr. Goss, and Mr. Barrett.—Mr. G. T. Baker read a paper entitled "Notes on the Lepidoptera collected in Madeira by the late T. Vernon-Wollaston." The paper was illustrated by a number of figures drawn and coloured some years ago by Prof. Westwood.—Mr. Hamilton H. Druce exhibited several very beautiful species of butterflies, belonging to the genus *Hypochrysops* from the Solomon Islands and Australia, and read a paper on them, entitled "A monograph of the Lycænoid genus *Hypochrysops*, with descriptions of new species."—Mr. C. J. Gahan read a paper entitled "Notes on some species of *Diabrotica*."

Linnean Society, December 4.—Prof. Stewart, President, in the chair.—The President exhibited some eggs of the shell slug, *Testacella haliotidea*, and briefly described the habits and mode of feeding of this mollusk. He also delineated and described the feeding tract of the snail.—Mr. F. J. George exhibited an autumnal flowering form of *Mercurialis perennis*, with stems four feet in length, which he had found at Preston, Lancashire.—Mr. R. A. Rolfe exhibited and made some remarks on a coloured drawing of *Cycnoches Rossianum*, showing both male and female inflorescences on the same pseudo bulb.—Mr. J. E. Harting exhibited an immature example of Bonaparte's gull, *Larus philadelphia*, Ord, of North America, which had been shot on the Cornish coast at Newlyn on October 24 last.—Mr. T. Christy exhibited and made remarks on some coca-leaves which had been forwarded from an East Indian plantation, and which were found to be superior to any received from South America.—On behalf of Mr. H. N. Ridley, of the Botanic Gardens at Singapore, Mr. B. D. Jackson read a paper on orchids, genus *Bromheadia*, on which some critical remarks were offered by Mr. R. A. Rolfe.—The next paper was one by Messrs. J. H. Lace and W. B. Hemsley on the vegetation of British Beluchistan, illustrated by a route-map showing the district in which Mr. Lace had been collecting. Seven hundred species were catalogued, amongst which were eleven new to science. The paper was ably criticized by Mr. C. B. Clarke, and Mr. J. G. Baker made some interesting observations on the peculiar prickly character of the vegetation which predominates in the hot and dry district explored.

Anthropological Institute, December 9.—Francis Galton, F.R.S., Vice-President, in the chair.—A paper on an apparent paradox in mental evolution, by the Hon. Lady Welby, was read.—Mr. Francis Galton, F.R.S., exhibited a large number of impressions of the bulbs of the thumb and fingers of human hands, showing the curves of the capillary ridges on the skin. These impressions are an unfailing mark of the identity of a person, since they do not vary from youth to age, and are different in different individuals. There is a statement that the Chinese—who seem to be credited with every new discovery—had used thumb impressions as proofs of identity for a long time; but Mr. Galton pronounced it to be an egregious error. Impressions of the thumb formed, indeed, a kind of oath or signature among the Chinese, but nothing more. Sir W. J. Herschell, however, when in the Civil Service of India, introduced the practice of imprinting finger-marks as a check on personation. Mr. Galton's impressions were taken from over 2000 persons by spreading a thin film of printers' ink on a plate of glass, then pressing the thumb or finger carefully on the plate to ink the papillary ridges, and afterwards printing the latter on a sheet of white paper. Typical forms can be discerned and traced, of which the individual forms are mere varieties. Wide departures from the typical form are very rare.

Mathematical Society, December 11.—Prof. Greenhill, F.R.S., President, in the chair.—The following communications were made:—On the reversion of partial differential expressions with two independent and two dependent variables, by E. B. Elliott.—Newton's classification of cubic curves, by W. W. R. Ball.—On the stability of a plane plate under thrusts in its own plane, with applications to the "buckling" of the sides of a ship, by G. H. Bryan (communicated by A. E. H. Love).—On the *q*-series derived from the elliptic and zeta functions of $\frac{1}{3}$K and $\frac{1}{4}$K, by Dr. Glaisher, F.R.S.—On the extension to matrices of any order of the quaternion symbols S and V, by Dr. Taber.—Steiner's poristic systems of spheres, by Prof. G. B. Mathews.

PARIS.

Academy of Sciences, Dec. 15.—M. Hermite in the chair.—The general relation of the state and increase of population, by M. Emile Levasseur. The relation is stated between the number of births, marriages, and deaths in France at different periods during this century. It appears that the proportion of suicidal deaths is increasing, although it is but 0·75 per cent. The illegitimate births amount to 7·5 per cent. in the period 1871–88, this proportion being about the mean illegitimacy of European nations. The number of male children born is known to be in excess of the number of female children; they become a minority, however, in the proportion of 57 to 61, because of the fact that the mean life of females is longer than that of men. All the statistics are graphically represented.—On the anomalous propagation of waves of sound, by M. Gouy.—On a modification of the electric gyroscope for the rectification of marine compasses, by M. G. Trouvé.—On the presence of very small quantities of aluminium in cast-iron and steel, by M. Adolphe Carnot.—On the increase of the number of red corpuscles in the blood of the inhabitants of the high plateaus of South America, by M. F. Viault.—On the development of the Copepodian parasite of Ascidiæ, by M. Eugène Canu.—On the localization of the active principle in the grain of Cruciferæ, by M. Léon Guignard.—On the structure of Peronosporæ, by M. L. Mangin.—Old observations of the vaccine tubercle of Leguminosæ, by M. Prillieux.—Synthesis of kainite and tachydrite, by M. A. de Schulten.—The depths of the Black Sea, by M. Venukof.

CONTENTS.

THURSDAY, JANUARY 1, 1891.

THE COMMON SOLE.

A Treatise on the Common Sole (Solea vulgaris), considered both as an Organism and as a Commodity. Prepared for the Marine Biological Association of the United Kingdom by J. T. Cunningham, M.A., F.R.S.E., late Fellow of University College, Oxford; Naturalist to the Association. (Plymouth: Published by the Marine Biological Association, 1890.)

THIS handsome monograph is (passing over the "Journal") the first-fruits of the Plymouth Laboratory. From the very outset, the Marine Biological Association has given a prominent place in its programme to economic matters. In the speeches at the foundation meeting, held on March 31, 1884, in the rooms of the Royal Society, and again on the occasion of the opening of the Laboratory at Plymouth, on June 30, 1888, the investigation of the habits and life-histories of important food-fishes, and other similar problems having a practical bearing upon fishing industries, was put forward as a primary function of the Association; and, in fact, the objects of the Association were officially stated to be "to promote accurate researches leading to the improvement of zoological and botanical science, and to an increase of our knowledge as regards the food, life-conditions, and habits of British food-fishes and molluscs." In response to this declared intention of dealing with the practical applications, the Fishmongers' Company have given most valued support to the Association from the beginning, and have subscribed largely to the funds, while H.M. Treasury has added £500 for five years to the annual income, on certain conditions.

In order to carry out efficiently this economic side of their work, and to fulfil their pledge with the Government and the public, the Council of the Association determined, in the summer of 1887, to appoint a skilled naturalist (in addition to the Resident Superintendent, now Director), who would carry on investigations into the natural history of British marine food-fishes, under the direction of the Council. To this post, Mr. J. T. Cunningham, who had been engaged for some years at similar work in connection with the Scottish Marine Station at Granton, was duly appointed, with special instructions from the Council to investigate the life-history of the common sole, with a view to practical results, and with the object of preparing an illustrated monograph on this fish. We now have the results of Mr. Cunningham's investigations before us.

It is now pretty generally recognized that results of economic value in connection with the fisheries can only be obtained, or looked for, as the result of properly conducted scientific investigations and carefully collected statistics. This first monograph issued by the Association is an excellent combination of material from these two sources of knowledge. It is a union of pure science and economics, made with the view of applying the results of scientific study to the extremely practical question of increasing the supply of soles to the market; and we find that it discusses that most important food-fish from almost every point of view. In determining the scope of the investigations and the general plan of the book, the guiding hand of Prof. Ray Lankester (to whose enthusiasm and energy the Association owes its existence and its success, and who has now succeeded Prof. Huxley in the presidential chair) is acknowledged by the author in the preface.

The work is divided into four parts, viz. Taxonomical, Morphological, Bionomical, and Economical. The first part deals with the classification and the characteristics of flat-fishes in general, and of the sole in particular. Throughout the book there is evidence that it is written, not for the professional biologist alone, but for the general public. The descriptions are not always in purely technical language, and at the beginning of each section, or when a fresh subject is entered upon, such as embryology (p. 84), we find a certain amount of elementary explanation which cannot be intended for the specialist, but may perhaps enable an intelligent non-professional reader to gain a general idea of the nature, objects, and results of each investigation, although he is not able to appreciate all the details. With the help of the hen's egg, the protoplasm and the food-yolk and the more important changes which take place in the young embryo are explained in a manner for which many may be grateful who are not aware of the significance of Kupffer's vesicle, and have no particular views on the nature of the periblast.

When, however, such explanations were being given, it would surely have been well to supplement the account of how to draw up the specific description of a flat-fish by an actual numerical example. The table on p. 15, or a part of it, or even a reference to it, might with advantage have been given at the foot of p. 10. There is no bibliography, beyond what naturally occurs in the taxonomy, and one is struck, in some parts of the book, by the absence of any reference to the work of previous investigators, so that it is difficult to know precisely how much is put forward as original; for example, under embryology there is no mention of the observations made by Prof. McIntosh and others.

In the morphological section there is a good account of the anatomy of the chief systems of the body, in which the most interesting passages are naturally those dealing with the modifications of structure caused by the remarkable "asymmetry of the Pleuronectidæ," which was first ably elucidated by Dr. Traquair more than twenty years ago. Mr. Cunningham, from his detailed study of the eye-muscles, supports the view that the twisting of the facial region of the skull, and the migration of the left eye on to the right (or upper) side in the adult is not the result of selection alone, but has been aided by the inheritance of characters or modifications acquired during the life of the individual. But this does not seem to follow as a necessary consequence of his observations and argument. For it is perfectly conceivable that anything which can be produced by the inheritance of acquired characters can also be brought about by the selection of congenital variations. It is true that "a man cannot lift himself up in a basket," and that (p. 53) "the eye-muscles could not by physiological effects have removed themselves bodily by their own action to a new position," but if there were enough men in baskets they might occur piled up ("congenitally") in such positions that some of them would form a series extending from the lower level to a higher; and, similarly, a series of selected congenital variations in muscles may form a gradation from the original position to a new one. I am not, however, objecting to a certain amount of inheritance of acquired characters coming in occasionally as a secondary factor—it is what I have always argued for of late years—but it does not seem to me that the present case yields any fresh evidence.

It is scarcely correct to say (p. 51) that evolutionists are divided into two schools at present, those who would interpret all modifications as the result of natural selection alone, and those who believe that acquired characters are inherited and that the modification "would take place without selection, while selection could not produce adaptations without the inheritance of acquired characters" (p. 52). These are rather the two extremes, and many biologists—judging at least by recently published opinions, and by the discussions in Section D at the last few meetings of the British Association—hold views of an intermediate nature. Probably all grades of opinion between the two extremes discussed by Mr. Cunningham will be found represented amongst leading evolutionists.

The remarks in regard to the origin of the follicle cells of the ovum are of interest in view of the controversy which has long waged as to the origin of the follicular epithelium and the "testa-zellen" in the Tunicata. Mr. Cunningham appears to incline to the view that the follicular epithelium is derived in bony fishes, not from the germinal epithelium, but from amœboid lymph-cells in the connective tissue. In Ascidians the most recent authorities agree in regarding the follicle cells as homologous with ova, and as being derived from germinal epithelium. Another interesting point is the modification of the right dorsal branch of the fifth nerve, and its explanation (p. 70).

One would like to know on what principles Mr. Cunningham has used his italics. It seems impossible to discover any from the book. This is a minor point, but not altogether unimportant. It is confusing to the reader to have italics used inconsistently, and besides it renders the difference of type meaningless. We find italics used indifferently for family titles, generic and specific names (for which they might with advantage have been retained), popular or local names, ordinary words requiring emphasis, and names of bones and other structures. But the type is not even used consistently for all of these. Why (on p. 50) should the "*recti*" muscles be in italics and not the "oblique"? Why (top of p. 67) should "*infundibulum*" be in italics when "cerebellum" and "medulla oblongata" are not, and why should "*hypophysis cerebri*" be favoured rather than "lobi inferiores" and "crura cerebri"? Then, again, we find (p. 68) "recti muscles" sometimes in italics and sometimes not.

At the end of the section on morphology there is a description of *Phyllonella soleæ*, a Trematode parasite which frequently occurs adhering to the skin of the fish (as shown in plate v.). By the way, why is there no explanation of the absence of Figs. 6 and 6*a*, which ought to illustrate this parasite, from plate xiv.? The woodcuts on p. 93 are probably the missing figures, but the matter as it stands, without any note of explanation, is rather mysterious. Plate xiv. and its description do not tally, and the figure labelled 6 is evidently 7.

Under the head of Part III., "Bionomical," are interesting articles on the geographical distribution, the habits, food, parasites, and enemies, the colours, and the breeding, development, and growth of the sole. Mr. Cunningham has determined the spawning season of the sole in his district to be from the middle of February to the end of April, but McIntosh and Prince state (Trans. R.S. Edin., vol. xxxv., p. 848) that off the eastern shores of Scotland the period extends to August. The observations on the colour, both in its detailed markings and its general effect, the variations under diverse circumstances, and the relation to environment, are particularly interesting, and the range, as shown in plates i. to iv., is certainly very wide. Mr. Cunningham finds that the change of colour which takes place when the fish is removed from one background to a differently coloured one is very rapid; a sole placed in a white porcelain dish begins to get lighter almost immediately.

The very beautifully coloured plates (plates i. to ix.) which illustrate especially this section on colour, are reproductions of water-colour drawings by Miss Annie Willis, and no doubt the original sketches are even more artistic representations of the actual objects. If one who has not seen the specimen drawn may criticize—and it is the very excellence that invites the critical spirit—one notices an absence of sufficient light and shade, and especially of high lights, in plate i. It is all too much at a dead level, as if a steam roller had been passed over fish and gravel, and had reduced them to a mosaic; but this is a fault common to many chromo-lithographs. In the present instance the effect of the plate is greatly improved by placing it at a considerable distance from the eye. If it is laid on the ground in a good light at 3 or 4 yards distance and looked down on, it looks as real and natural as can be expected from any representation which is produced by a mechanical process and therefore wants the subtle vivacity of the artist's actual hand-touch.

The fourth and last part, "Economical," is divided into sections on artificial propagation, the sole fishery, and practical measures. Looked at from the economic point of view, this most estimable fish is of interest to everyone. It is said that many Americans come over to England every year for the express purpose of indulging in fresh fried soles for breakfast. Is it with a view of affecting the demand that Mr. Cunningham tells us that our sole may have been swallowed by a *Lophius* a day or two before we meet it at table, and then disgorged on the deck of the trawler? It would be kinder of him to reduce the market price (which appears to be rising steadily, and has increased fourfold since 1856) by increasing the supply of soles by some such process of artificial fertilization on a large scale as that proposed on p. 147. A considerable practical difficulty will, however, probably be encountered in the remarkably unenlarged condition of the testes in the male sole, and the difficulty of distinguishing the milt from mucus and sea-water, especially if the stripping of the fish is to be conducted by the trawlers themselves. Everyone, both on the scientific and on the economic side, will look with deep interest for the results of the further observations and experiments to be made by the staff of the Plymouth Laboratory on these practical questions.

A few misprints (none of great moment) have been noticed in reading over the book, viz. "ectetmoid" (p. 53), "an" for on (p. 61), "Kupher's" vesicle (p. 120), and Fig. 3 for Fig. 5 (p. 123, foot); while a slip occurs near the foot of p. 50 in the phrase "those of the dorsal or right eye," since the dorsal eye in the sole is the left.

The book, as a whole, is good, and forms an interesting and important contribution to our slender list of monographs of British animals, and on account of its economic side will, no doubt, interest a wider circle of readers than is usually the case with zoological works. The Marine Biological Association are to be congratulated on the appearance of their first memoir, and it is hoped that others of the series will speedily follow.

W. A. HERDMAN.

WOOD-WORKING.

Exercises in Wood-working, with a Short Treatise on Wood, written for Manual Training Classes in Schools and Colleges. By Ivin Sickels, M.S., M.D. (New York: D. Appleton and Company. London: W. Allen and Co., 1890.)

THIS is, in some respects, a more interesting work than its title would seem to indicate. Of late years, since it has been recognized that manual or practically industrial training of some kind should form a part of the education of every child, books of this kind have greatly improved in every respect, because it has become more necessary to make them thorough in details, and at the same time present them in such clear and succinct language that they may be perfectly intelligible to youthful minds. And as the interest in the subject of technical education is rapidly increasing, and with it the demand for good manuals, it is not without pleasure that we welcome a work which fulfils admirably what is requisite for its purpose. The author, in an introduction which we could wish had been longer, remarks that the tendency of modern systems of education is towards a proper distribution of practical with theoretical training—that is, manual with "literary" education—and that the *mind* is to be aided in its development by the action of the eye and hand. "The prime object of all manual training is to aid mental development." This is a very great and little-known truth, which was first fully set forth in a work entitled "Practical Education," by C. G. Leland, in which it was shown that, out of 110,000 children in the public schools of Philadelphia, the 200 who attended industrial art classes, and who were chosen at random for them, were the first in *all* studies, such as arithmetic or geography; that is to say, it has been proved by years of careful experiment on a very large scale, that if we take two children of equal capacity, following the same studies in the same school, and let one of these have at the same time from two to four hours' weekly training in design, modelling, wood-carving, and carpenters' work, &c., the latter will invariably take precedence in all the ordinary school studies, so much is the mind impressed by industrial art culture. The recognition of this principle by a practical teacher like Dr. Sickels indicates that his work is written in accordance with the most advanced ideas on the subject of technical education.

The author begins by giving in Part I. a sufficiently detailed description of the structure of wood of different kinds, its composition and manner of growth, the season for cutting trees, drying of wood, and warping, its properties, measure, and value, with an account of the twenty-five kinds most generally used. In describing wood-working trades, he declares there are only two, carpentry and joinery, carving and turning being only "adjuncts" to joinery; a degradation of wood-carving with which we should suppose few would agree. It is difficult for us, with a magnificent fourteenth century carved wood image of the Virgin and Child before us as we write, to comprehend what it has in common with "joinery," while, as regards turnery, the great and admirable work of John J. Holtzapfel, certainly establishes its claim to be an independent art. "But these be trifles." The principal part of the work, or about one hundred pages, which is copiously illustrated with pictures which are all intelligible at a glance (not an *invariable* thing in such works), is, on the whole, without errors. It treats of carpenters' tools (those for wood-carving are not included, but should have been) and their use in detail, this portion being admirably executed; the construction of joints, which is, on the whole, the most difficult and interesting part of the wood-worker's art, being very well written. The student who wishes, however, to be perfect in this, should also consult "Forty Lessons in Carpentry Practice," by C. F. Mitchell (London: Cassell and Co.), a little book of great value. The mysteries of the mitre joint, stretchers, dowels, and dovetailing, have, however, never been treated more cleverly or clearly than by Dr. Sickels Among remaining topics are drawers, framing—of which we have by no means enough, though "good, what there is of it"—laying floors, trimming, and the construction of all the minor details, such as doors, stairs, sashes, and hand-rails. This portion of the work would be of great practical value to settlers in the wilderness, who would often like to build for themselves houses, yet know not how. We believe that the world, however, still lacks a work teaching men all the art of making shelters and homes, from building wigwams or adjusting stones and boughs for a night's lodging, up to log huts, Pictish "bee-hives," box cottages, "and so wider." As regards typographical details, paper, and binding, this work is all that could be expected.

BACTERIA.

Les Bactéries et leur rôle dans l'Étiologie, l'Anatomie, et l'Histologie pathologiques des Maladies Infectieuses. Par A. V. Cornil et V. Babes. Third Edition, in Two Volumes. (Paris: Félix Alcan, 1890.)

THIS enlarged edition treats of the whole range of pathogenic and to a certain extent also of non-pathogenic bacteria in a fairly exhaustive manner. The classification, the chemical nature, the biological characters, the methods used in their study, both in cultures and in staining them in animal tissues, are described in a lucid though rather a dogmatic fashion. The *rôle* and the nature of the *rôle* the pathogenic bacteria play in relation to infectious diseases are, as the title indicates, the principal subjects of the book, and we have no hesitation in saying that the authors have produced a very creditable work. But there are a number of diseases of the lower animals described here, in which the demonstration of bacteria in microscopic sections through one or the other of the diseased organs is sufficient for the authors to assign to those bacteria a specific character; more than this, every granule which appears stained in those sections is regarded by the authors as a microbe. The exact proof, and even attempt at exact proof, that this is so is omitted in many of these cases.

The illustrations accompanying the text are very numerous, many of them in colours: amongst these latter some are very excellent and true to nature, *e.g.* those illustrating the chapter on tuberculosis; many others are decidedly bad and erroneous, *e.g.* most of the illustrations of cultivations, and some of the sections stained in one or two colours, while many others are badly printed. We fail to see the use of such a confusing and diagrammatic crowd of illustrations as form plate i. The authors give numerous references to other workers, but there is, we think, a rather large dose of reference to their own works, such reference occurring in remarkable sameness. In several instances they do not seem to have read the original statements of their references. Thus, for instance, Cornil and Chantemesse in 1887 described and illustrated the pathology of the disease known in England as swine fever; they describe it under the name of "pneumo-entérite des porcs," both the name and the pathology of which disease have been minutely described and copiously illustrated in the Reports of the Medical Office of the Local Government Board for 1878-79, under the name of "infectious pneumo-enteritis of the pig." If they had really read the text in that English Blue-book, and inspected the illustrations of the pathology of our infectious pneumo-enteritis of the pig, they could not have failed to see that they are using the same name for the same disease, viz. they would have recognized the identity of the English and French disease; as a matter of fact, they give us erroneously to understand that our infectious pneumo-enteritis is the French "rouget de porcs," a disease utterly different from it.

There are various assumptions as regards the biology of certain specific bacteria, for which not even an attempt at proof is undertaken. Thus the authors ascribe to the bacillus of diphtheria and the bacillus of typhoid fever the power to form spores, and this deduction they make from certain differentiated granules in the bacilli brought out by staining; but every bacteriologist knows very well that such proof is valueless, unless the alleged spores have been observed to be able to germinate; and unless certain experimental evidence (drying, heating, action of antiseptics) is forthcoming, no one would be justified in concluding that those granules in bacilli are spores.

Though the work, as has been remarked, is not all that could be wished, it nevertheless deserves to take a high place amongst the text-books on bacteriology. It is written in a very lucid style, and abounds in valuable and original observations.

OUR BOOK SHELF.

Verslag omtrent den Staat van 'S Lands Plantentuin te Buitenzorg en de daarbij behoorende Inrichtingen over het Jaar 1889 ("Report on the Condition of the State Gardens at Buitenzorg"). (Batavia: Government Printing Office, 1890.)

UNDER the able direction of Dr. Treub, the author of the Report before us, the botanic garden at Buitenzorg in Java has developed into one of the most important establishments of the kind in existence, and has become an active centre of both scientific and practical botany. The present Report renders an account of the staff, publications, library, herbarium, museum, botanical laboratory, chemical-pharmacological laboratory, botanical garden, experimental garden for trials of trees producing gutta-percha, together with copious lists of plants and seeds distributed and received. As usual during the past few years, a number of foreigners, chiefly Germans, have occupied tables in the laboratory, having travelled from Europe expressly for the purpose of availing themselves of the facilities there afforded for original researches. This Report is recommended to botanists contemplating work in the tropics. W. B. H.

The Electric Light. Fifth Edition. By A. Bromley Holmes, M.Inst.C.E. (London: Bemrose and Sons, 1890.)

QUITE recently we had occasion to refer to the rapid growth that has taken place during the last few years in the development and application of electricity, and at the same time we gave an illustration of one of the latest forms of gas-engines for its production. This work places before the reader (who is assumed to be quite ignorant of electrical science) a popular and intelligent account "of the means used for producing electric light." The author, at the commencement, conscious of the difficulty of employing technical terms, explains each in simple language, so that their meanings may be fairly grasped by the reader.

After showing how electricity can be produced by batteries, he explains how it may be produced by mechanical means, leading up to the latest forms of dynamos. A very meagre description is given of these dynamos, descriptions of which, if they had been more fully treated, would have added great interest to this part of the work.

Conversion of electricity into light, and storage of electricity, are the subjects of the next two chapters, in the former of which are described the various lamps employed in lighting, with an account of the many self-adjusting arrangements for the purpose of keeping the carbon poles at a constant distance from each other. The remaining chapters deal with the distribution and measurement of electricity, testing and necessary precautions, and selection of light, in which the selection of lamp and the arrangements for any particular purposes are discussed. The author also treats of motive power and cost, concerning the latter of which he gives some interesting statistics relating to the comparison of gas and electricity.

On the whole, the author has produced an interesting book, which explains in a simple manner the elements of electric lighting.

Maps and Map-Drawing. By William A. Elderton. "Macmillan's Geographical Series." (London: Macmillan and Co., 1890.)

THIS little book will be found to form a most useful supplement to the works on geography published in the same series. In it an excellent brief account is given concerning the history of maps from the records of the Egyptians down to the present day. Then follow various methods of making surveys, including descriptions of the various instruments employed, such as the prismatic compass theodolite, sextant, &c. In the section on the globes, a short summary is given of ancient and curious globes, succeeding which are descriptions showing how latitudes and longitudes, day and night, &c., are measured, also the principles of great circle sailing. Part iv. deals with map-drawing, in which a brief but plain description is given of the various methods of projection, such as orthographic, gnomonic, stereographic, conical, &c.; reference also is made to the different symbols used in map-drawing. The last two parts treat of map copying and memory-maps, of which the latter will be found of great importance, for, by using the method adopted, and carrying out the suggestions, the learner may remember much that might otherwise be forgotten.

Krystallographisch-chemische Tabellen. Von Dr. A. Fock. (Leipzig: Wilhelm Engelmann, 1890.)

THIS little work of ninety pages supplies a much-needed want in chemical crystallography. The increase of late years in the number of original memoirs, describing the crystallograpical characters of newly-discovered chemical compounds, and pointing out relations between many of the longer known ones, has been so great that the text-books now in use, such as that of Rammelsberg, are very much out of date. Dr. Fock presents the data acquired up to the present in a very condensed and easily referable form; a form, moreover, which at once exhibits such relationships as have been noticed between chemical composition and crystalline form. The tables will be found to include brief descriptions of all the more recent measurements contributed to the *Zeitschrift für Krystallographie*, as far as regards the crystalline system and the elements of the crystals measured. The arrangement adopted is somewhat similar to that in Groth's "Tabellarischer Uebersicht des Mineralien," but including in addition almost all the known chemical salts, and all the measurements of organic compounds yet made. The information furnished concerning each of the compounds mentioned consists of (1) its symmetry, (2) the ratio of its axes, (3) the axial angles of monoclinic and triclinic compounds, and (4) the observer by whom the measurements were made. In many places, where important relations have been noticed, additional information of a character extremely useful for lecture purposes is given. It is quite evident from the whole character of the work that great care and a large expenditure of time have been involved in its preparation, and those who are interested in the subject must feel greatly indebted to Dr. Fock for collecting such a valuable store of information in so handy a form.

A. E. TUTTON.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. Wallace on Physiological Selection.

BY his second letter Mr. Wallace leaves no possibility of doubt touching (1) the manifest agreement, and (2) the alleged difference, between his recent theory of cross-infertility in relation to the origin of species, and the preceding theory on the same subject, as published by Mr. Catchpool, Mr. Gulick, and myself.

(1) The manifest agreement consists in supposing, as he says, that some amount of infertility characterizes the distinct varieties which are in process of differentiation into species; and that such "incipient infertility" is of so much importance in this "process of differentiation" that its absence may be regarded as one of the *usual* causes of the failure of varieties to become developed into distinct species.

(2) The only point of difference alleged is, that while Mr. Wallace says this incipient infertility can *never* arise alone, or except in association with some other and preceding varietal difference, we (according to him) have represented that it must *always* arise "alone, in an otherwise undifferentiated species," and therefore always constitute the *initial* change in the way of varietal divergence.

Such being the only point of difference alleged, it is obvious in the first place that the allegation, even if valid, has reference to a point of but secondary importance. For if we are all agreed that the "incipient infertility," whenever it does arise, is a factor of such high importance in the origination of species as Mr. Wallace now admits, surely the question whether it can ever arise before (or can only arise after) incipient varietal characters of any other kind becomes a question of comparatively little consequence. But now, in the second place, the allegation is not valid, being, in fact, the very opposite of the truth. Taking first my own presentation of the theory, both in "the original paper and in the summary of it published in NATURE," I not only expressly stated, but carefully argued, that the incipient infertility may arise *either before or after* variations of any other kind; and, in order to emphasize this distinction, I devoted one part of the paper to the first class of cases, while relegating to another part my consideration of the second class. Therefore it is merely by an eclectic method of quotation that Mr. Wallace now represents that I began by setting forth only one side of "physiological selection," or the cases where incipient infertility is the prior change. Why he should persistently ignore all the other part of the same paper, or the cases where I show that incipient infertility need not be the prior change, I do not care to inquire. But at least the omission cannot be due to any want of clearness on my part, inasmuch as in his first criticism of the paper, which he published several years ago, he displayed a complete understanding of what I had said upon this point.[1]

After this much explanation it seems almost needless to say that I stand by every one of the "eight quotations" which Mr. Wallace has given. For "it [still] appears to me much the more rational view that the primary specific distinction is likewise, as a rule, the primordial distinction; and that the cases where it has been superinduced by the secondary distinctions are comparatively few in number;" "it is [still] on what may be called spontaneous variability of the reproductive system itself that I mainly rely for evidence of physiological selection;" I still continue to ask, "Why should we suppose that, unlike all other variations, it [*i.e.* the physiological variation] can never be independent?" And so on through all the eight selected sentences, provided that any regard at all be paid to their context and relation to other parts of the paper. For no one of these sentences in the smallest degree affects the position which from the first I have consistently and persistently held—viz. that it makes no difference to the theory in what proportional number of cases the physiological change has been the prior change. Indeed, the *immediate* context of the first of the above quotations sets forth that it would make no difference to the theory even if we were to suppose that in *no* case can the physiological change have been the prior change.[2] In other words, it is expressly stated that, even if we were to adopt the identical opinion on which alone Mr. Wallace now relies as constituting any difference at all between his theory and my own, still the latter, in its "principle" or "essence," would be in nowise affected. Yet Mr. Wallace now accuses me of "an absolute change of front" on the sole ground that I repeat these statements![3]

So much for my own paper. Mr. Catchpool's enunciation of the theory was much too brief to admit of any fair criticism of the kind which Mr. Wallace now passes upon it. But Mr. Gulick's elaborate essays—which he abstains from mentioning—are quite another matter; and, as stated in my last letter, they considered much more fully than mine had done the subordinate

[1] *E.g.*, "Mr. Romanes then goes on to argue that, as a rule, these physiological variations are those which occur first, and form the starting-point of new species. He admits that in some ['possibly in many'] cases sterility may be a secondary character, due perhaps to the constitutional change indicated by the external variation; but even in that case physiological selection plays an equally important part, because if it [*i.e.* the incipient infertility] does not arise, either coincidently with the ordinary external variation, or as a consequence of it, then that variation will not be preserved, but will rapidly be extinguished by intercrossing with the parent form" (*Fortnightly Review*, 1886, p. 302). This brief extract is enough to show how widely Mr. Wallace's first representation of my "original paper" differs from his last, as regards the only point now in question.

[2] See NATURE abstract, vol. xxxiv. p. 339.

[3] There are several other distortions of my views in Mr. Wallace's letter, but space prevents me from dealing with them.

question at present before us. In the result Mr. Gulick completely agreed with me, that it cannot signify *how* or *when* the physiological variation of initial cross-infertility arises; for to whatever *causes* it may be due, and at whatever *time* in the process of varietal divergence it may first occur, it must alike furnish as highly important a condition to the origination of species as Mr. Wallace has eventually himself assigned to it.

I say "eventually," because Mr. Wallace has never before expressed himself to the effect that, in his opinion, cross-infertility is a factor of such prime importance in the origination of species. Why has he never done so? Surely the matter is one of sufficient magnitude to have justified some mention in one or other of the many valuable "contributions" which he has made to the theory of evolution. Or, not to go further than his past criticisms of my own paper on the subject, what pages of controversy he might have saved in this journal and elsewhere by stating, at any time within the last four years, that he had no disagreement with me touching the probable occurrence, and the important consequence, of some degree of infertility characterizing varieties which afterwards, and on this account, develop into species; but merely doubted whether any degree of infertility could ever arise before differentiation of some other kind had begun to take place. Such criticism would have been mild indeed. But hitherto the crown and front of opposition to the theory of physiological selection has been that, in representing cross-infertility as a factor of any great importance in the origination of species, the theory is not only untrue in itself, but tends to "shrivel up natural selection to very small dimensions." Now, however, criticism "changes front." It is no longer denied, but actually upheld, that "selective fertility" is as highly important a "co-operative cause in the origination of species" as I have ever claimed; and the new attack is directed only to a very subordinate point—a point, moreover, which both Mr. Gulick and myself had expressly anticipated, fully discussed, and shown not to belong to "the essence of the theory."[1]

Oxford, December 22, 1890. GEORGE J. ROMANES.

[1] P.S.—Mr. Wallace alludes to my "standards of scientific reasoning and literary consistency." As regards the former, I am satisfied with a full and independent corroboration by a consistent and a logical mind. As regards the latter, it is enough to quote the concluding words of my reply to Mr Wallace's first criticism of four years ago:—"The *main* feature of the theory is what my paper states it to be—viz. that sterility with parent forms is one of the *conditions*, and not *always* one of the *results*, of specific differentiation. But, if so, is it not evident that all causes which induce sterility are comprised by the theory, whether these causes happen to affect a few individuals sporadically, a number of individuals simultaneously, or even the majority of an entire species?" (*Nineteenth Century*, January 1887). And is it not equally evident, as elsewhere stated, that it does not signify whether the sterility arises before or after the "differentiation" has begun; seeing that, in either case, without the sterility the differentiation (as Mr Wallace now says) will usually fail to proceed to the formation of distinct species? I have no space to discuss Mr. Darwin's views on this subject; but assuredly they are far from those which are expressed either here or in "Darwinism."

Molecular Dispersion.

IN the notes that appeared in your journal of December 11 (p. 133), you gave a very full account of some papers lately published in the *Bulletin de la Société Chimique de Paris*, on optical dispersion, by Messrs. Barbier and Roux.

This investigation is a remarkable instance of how laborious and intelligent work may be almost wholly thrown away for want of the knowledge of what has been previously done in the same direction. The authors commence their first paper with the astounding statement: "Dispersion has never been studied from the point of view of the relations which connect this physical property of bodies with their composition, their molecular weight, and their chemical constitution." This, however, was attempted by Sir John Herschel more than half a century ago, though with little success: and most of the scientific men who have best elucidated the subject of molecular refraction, such as Mascart, Brühl, and Nasini, have paid some attention also to dispersion. Mr. Dale and I gave numerical values for dispersion equivalents, analogous to Landolt's "refraction equivalents," for CH_2, Cl, &c., as far back as 1866. The dispersion of isomeric bodies was treated by me in 1881; and within the last few years I have communicated papers on the subject of molecular dispersion to learned Societies in England, France, and Switzerland. Some of the substances worked on by Messrs. Barbier and Roux have not, I think, been optically examined before; but the value of their careful observations is much diminished by their having measured two lines of the tin spectrum, instead of the A and H of the solar spectrum, or the α and γ of that of hydrogen; thus their results cannot easily be compared with the hundreds of measurements of dispersion already published by others. They have unfortunately employed Cauchy's formula, and have taken as the "specific dispersive power," $\frac{B}{d}$; that is, Cauchy's B divided by the density of the substance, instead of $\frac{n_a - n_b}{d}$, the difference between the refraction of two lines divided by the density. Brühl commenced to work in the same way, but shows in a paper in *Liebig's Annalen* for August 1886 that the method is unsatisfactory. The generalizations of our present authors are definite, and apparently correct, but they could have been mostly foreseen and explained if they had more clearly grasped the idea of molecular dispersion.

In the early summer I sent Messrs. Barbier and Roux copies of my papers on the subject; on August 1 they acknowledged receipt, and promised to refer in a forthcoming paper to previous work. As the paper reviewed in NATURE appeared in a preliminary abstract in the *Comptes rendus* of July, it is evident that they have yet something to bring before the public.

J. H. GLADSTONE.

17 Pembridge Square, December 27, 1890.

Weighing with a Ternary Series of Weights.

IN a former communication (NATURE, November 13, p. 30) I omitted, in order to avoid prolixity, to show how readily any given number may be expressed in the notation therein proposed. To effect this, it is only necessary to express the given number in the ternary scale, and then, beginning on the right, to substitute for 2, wherever it occurs, − 1, whilst increasing the previous figure by 1. When 3 occurs in the application of this rule, it must of course be replaced by 0, the previous figure being again increased by 1.

Examples:—

41 is in ternary notation			1112, in new notation			**11111.**
500	,,	,,	,, 200112,	,,	,,	**1101111.**
71	,,	,,	,, 2122,	,,	,,	**10101.**

Or (still more briefly) in dividing by 3, to express the number in the ternary scale, we may substitute for the remainder 2, wherever it occurs, − 1, and increase the quotient by 1.

Examples:—

425			474			500		
142	remainder	− 1	158	remainder	0	167	remainder	− 1
47	,,	1	53	,,	− 1	56	,,	− 1
16	,,	− 1	18	,,	− 1	19	,,	− 1
5	,,	1	6	,,	0	6	,,	1
2	,,	− 1	2	,,	0	2	,,	0
1	,,	− 1	1	,,	− 1	1	,,	− 1
0	,,	1	0	,,	1	0	,,	1
$3+27+729$ $-(1+9+81+243)$			$729-(3+9+243)$			$27+729$ $-(1+3+9+243)$		

Bradford, December 13, 1890. J. WILLIS.

PROF. EVERETT's rule (NATURE, December 4, p. 104) is needlessly complicated. All that is necessary is to express the given weight in the ternary scale with digits that are either 0, + 1, or − 1. His example is thus solved:—

3)500
3)167 − 1
3)56 − 1
3)19 − 1
3)6 + 1
3)2 + 0
1 − 1 or $500 = 1\bar{1}01\bar{1}\bar{1}\bar{1}$ ternary

$$= 729 - 243 + 27 - 9 - 3 - 1.$$

We thus see generally that, to express weights in units and powers of n, we must be provided with $\frac{1}{2}n$ or $\frac{1}{2}(n-1)$ balance-weights of each sort, according as n is even or odd; and that then any given weight can be expressed in a single way only if n is odd. R. E. B.

I AM glad to have elicited a simple and direct rule for the required distribution, to obviate the necessity of a tedious tentative process, or of the reference to tables suggested in Mr. Willis's first letter. My own rule effected the desired object, but the device of admitting negative as well as positive remainders in the successive divisions by 3 is a decided improvement. R. E. B.'s method is identical with Mr. Willis's second method, and is undoubtedly the best. Its relation to my method is seen by noting that $\frac{1}{2}(2^7 - 1)$ is ternary 1111111, which, being added to $1\bar{1}01\bar{1}\bar{1}\bar{1}$, converts it into 2012000. My rule might have been generalized by adding (instead of *the least* value) *any* value of $\frac{1}{2}(2^n - 1)$ that exceeds the given weight.

In connection with Mr. Willis's suggestion (in his first letter) of tables for finding what number a person has thought of, I may mention that I published through Simpkin and Marshall, nearly forty years ago, a set of 4 cards for this purpose under the name of "Sibylline Leaves," of which a few specimens are still in my possession. Taking advantage of the fact that weights of 1, 3, 9, 27 will make up any integer from -40 to $+40$, that is 81 different integers when 0 is included, the numbers on the cards ran from 1 to 81. The computation consisted in taking 41 to start with, and adding or subtracting 1, 3, 9, or 27, two kinds of type being employed to distinguish between addition and subtraction. J. D. EVERETT.

The Composition of Sea-Water.

COULD any reader of NATURE who may have given attention to the subject offer some explanation of the fact that the water of the sea contains such a very large excess of sodium salts relatively to salts of potassium?

Many of us have thought about the question, and heard it discussed, but I am not aware that any satisfactory conclusion has been arrived at.

I think it is usually assumed that the salts in the ocean have been mainly derived from the solutions carried in by rivers; solutions formed during the waste of rocks at the surface, or brought up by springs. Alkaline salts in such solutions will be principally due to the decay of felspars; and if we consider the rocks of the earth's crust, we find that the potash-felspars very much exceed in quantity the soda-felspars. It used to be considered that in earlier geological periods the "acid," mainly potash-bearing rocks, so enormously exceeded the "basic" rocks, in which the soda-felspars occur principally, that these latter were relatively quite insignificant in amount. Later petrographical work tends to show that this preponderance may not have been so large as was once supposed, but still there is no question that the excess of the potash-bearing rocks was, and is, very great. We might therefore look for more potash than soda in the drainage waters. We find, however, that in the sea, and in the rivers, the reverse is the case. Instances are, indeed, quoted (Roth, "Chemische Geologie") of rivers with more potash than soda in solution, but only as exceptions, and at points where only granite and gneiss had been drained.

This excess of soda in river-waters may be explained by the fact that though more potash-rocks are exposed than soda-rocks, yet the more rapid decay of the soda-lime felspars causes the proportions of the dissolved salts to be such as we find them: though this would hardly suffice to explain the great difference we find in the ocean.

Some people, again, assume that the composition of sea-water, though it may have been modified by the river-waters, is due to the constituents which were contained in the original first ocean as it condensed on the surface of the cooling earth—the "Urmeer" of the Germans; and Roth points out, in discussing analyses of river-waters and sea-water, that the composition of the former is such that they never could be the cause of the present composition of the latter.

This going back to the original ocean may be, as indeed it seems to be, the only explanation open to us, but it is not without its weak points. If potash-salts so greatly exceed soda-salts in the earth's crust now, we may assume that the same relative proportions existed, more or less, when the whole mass was still gaseous; and it is not easy to see any reason why, when cooling and condensation had allowed of the formation of a mass of molten silicates, the sodium-salts should have remained in great excess in the still uncondensed heated atmosphere out of which the "Urmeer" would eventually be deposited on the cooling crust. Mere difference of volatility of the respective salts would not suffice to account for this; and if we are to take the hypothesis at all, we must perhaps assume that when a low enough temperature had been reached to allow of the combination of the respective elements to molten silicates, the potassium, as the stronger base, would be taken more largely into these combinations by preference to the sodium, which would partly remain in the still intensely heated atmosphere, to be condensed with other vapours at a later period. M.

Birds' Nests.

IN addition to your "curious places for birds' nests," I give you my own experience between 1842 and 1882 at Highfield House, Nottinghamshire.

Redbreast for four consecutive years on a shelf.

Redbreast in a fern (*Platycerium alcicorne*) for four consecutive years.

Redbreast in a *Strelitzia regina* plant.

Hedge Warbler in a tall Fuchsia in a greenhouse.

Chiff Chaff in a fern (two years).

Pied Wagtail on a shelf in vinery (two years).

Flycatcher on hinge of door (ten consecutive years).

Flycatcher on ledge of thermometer stand (three years).

Wren in a Daniels's hygrometer stand.

County Club, Chepstow. E. J. LOWE.

Butterflies Bathing.

IN answer to the inquiry of Mr. G. A. Freeman (NATURE, vol. xlii. p. 545) as to the food and habits of *Papilio macleayanus*, the butterfly which has been observed to visit water apparently for the purpose of performing its ablutions, I may inform him that the species is commonly found about Sydney, where it feeds in its larval condition on the camphor laurel (*Laurus camphora*), and the tender shoots and leaves of the orange. It certainly is not aquatic during any part of its life, nor do the plants upon which it feeds grow near water; the insect simply follows the example of its brothers, depositing its eggs singly, and undergoing the transformations on the food-plant as any reasonable butterfly should. Mr. G. Lyell's note as to the bathing habits of *P. macleayanus* is most interesting, and as far as I am aware the observation is entirely new, although many butterflies of the family Lycænidæ frequent pools on very hot days, settling on the mud at their margins, probably in search of a little moisture. Only recently at Toowoomba, in Queensland, I noticed a number of *Holochila absimilis* settled about puddles formed on the roads by a passing shower.

A. SIDNEY OLLIFF.

Department of Agriculture, Macquarie Street, Sydney, November 11, 1890.

THE RESEARCHES OF DR. R. KŒNIG ON THE PHYSICAL BASIS OF MUSICAL SOUNDS.[1]

I.

NOT often does it fall to the lot of a scientific man to become the mouthpiece of another whose researches have lasted over a quarter of a century; yet this is the enviable position in which I find myself on this occasion as the spokesman of Dr. Rudolph Kœnig, who is known not only as the constructor of the finest acoustical instruments in the world, but as an investigator of great originality and distinction, and author of numerous memoirs on acoustics. Dr. Kœnig, who has of late made very important contributions to our knowledge of the physical basis of music, using apparatus immeasurably superior to any hitherto employed in experimental investigations of this subject, has on various occasions, when I have visited him in Paris, shown me these instruments, and repeated to me the results of his researches. Important as these

[1] By Prof. Silvanus P. Thompson. (Communicated by the author, having been read to the Physical Society of London, May 16, 1890.)

are, they are all too little known in this country, even by the professors of physics. It was, therefore, with no little satisfaction that the Council of the Physical Society learned that Dr. Kœnig was willing to send over to London for exhibition on this occasion the instruments and apparatus used in these researches. And their satisfaction to-day is heightened by the fact that Dr. Kœnig has himself very kindly come over to demonstrate his own researches, and has given us the opportunity to welcome him personally amongst us.

The splendid apparatus around me belongs to Dr. Kœnig, and forms but a very small part of the collection which adorns his *atélier* on the Quai d'Anjou. He lives and works in seclusion, surrounded by his instruments, even as our own Faraday lived and worked amongst his electric and magnetic apparatus. His great tonometer, now nearly completed, comprises a set of standard tuning-forks, adjusted each one by his own hands, ranging from 20 vibrations per second up to nearly 40,000, with perfect continuity, many of the forks being furnished with sliding adjustments, so as to give by actual marks upon them any desired number of vibrations within their own limits. Beside this colossal masterpiece, Dr. Kœnig's collection includes several large wave-sirens, and innumerable pieces of apparatus in which his ingenious manometric flames are adapted to acoustical investigation. There also stands his tonometric clock, a timepiece governed, not by a pendulum, but by a standard tuning-fork, the rate of vibration of which it accurately records.

It is not surprising that one who lives amongst the instruments of his own creation, and who is familiar with their every detail, should discover amongst their properties things which others whose acquaintance with them is less intimate have either overlooked or only imperfectly discerned. If he has in his researches advanced propositions which contradict, or seem to contradict, the accepted doctrines of the professors of natural philosophy, it is not that he deems himself one whit more able than they to offer mathematical or philosophical explanations of them: it is because, with his unique opportunities of ascertaining the facts by daily observation and usage, he is impelled to state what those facts are, and to propound generalized statements of them, even though those facts and generalized statements differ from those at present commonly received and supposed to be true.

At the very foundations of the physical theory of music stand three questions of vital importance:—

(1) Why is it that the ear is pleased by a succession of sounds belonging to a certain particular set called a scale?

(2) Why is it that when two (or more) musical sounds are simultaneously sounded, the ear finds some combinations agreeable and others disagreeable?

(3) Why is it that a note sounded on a musical instrument of one sort is different from, and is distinguishable from, the same note sounded with equal loudness upon an instrument of another sort?

These three queries involve the origin of *melody*, the cause of *harmony*, and the reason of *timbre*.

The theories which have been framed to account for each of these three features of music are based on a double foundation—partly physical, partly physiological. With the physiological aspect of this foundation we have to-night nothing to do, being concerned only with the physical aspect. What, then, are the physical foundations of melody, of harmony, and of timbre? Demonstrable by experiment they must be, in common with all other physical facts, otherwise they cannot be accepted as proven. What are the facts, and how can they be demonstrated?

We are not here, however, to fight over again the battle of the temperaments, nor do I purpose to enter upon a discussion of the origin of melody, which, indeed, I believe to be associative rather than physical. I shall confine myself to two matters only, with which the recent researches of Dr. Kœnig are concerned—the *cause of harmony* and the *nature of timbres*. Returning, then, to the ratios of the vibration numbers of the major scale, we may note that two of these, namely, the ratios 9 : 8 and 15 : 8, which correspond to the intervals called the major whole tone and the seventh, are dissonant—or, at least, are usually so regarded. It will also be noticed that these particular fractions are more complex than those that represent the consonant intervals. This naturally raises the question: *Why is it that the consonant intervals should be represented by ratios made up of the numbers* 1 : 6, *and by no others?*

To this problem the only answer for long was the entirely evasive and metaphysical one that the mind instinctively delights in order and number. The true answer, or rather the first approximation to a true answer, was only given about forty years ago, when von Helmholtz, as the result of his ever-memorable researches on the sensations of tone, returned the reply: *Because only by fulfilling numerical relations which are at once exact and simple can the "beats" be avoided which are the cause of dissonance.* The phenomenon of beats is so well known that I may assume the term to be familiar. An excellent mode of making beats audible to a large audience is to place upon a wind-chest two organ-pipes tuned to $ut_2 = 128$, and then flatten one of them slightly by holding a finger in front of its mouth. Von Helmholtz's theory of dissonance may be briefly summarized by saying that any two notes are discordant if their vibration numbers are such that they produce beats, maximum discordance occurring when the beats occur at about 33 per second; beats if either fewer than these, or more numerous, being less disagreeable than beats at this frequency. It is an immediate consequence that the degree of dissonance of any given interval will depend on its position on the scale. For example, the interval of the major whole tone, represented by the ratio 9 : 8, produces four beats per second at the bottom of the pianoforte keyboard, 32 beats per second at the middle of the keyboard, and 256 beats per second at the top. Such an interval ought to be discordant, therefore, in the middle octaves of the scale only.

To this view of von Helmholtz it was at first objected that, if that were all, all intervals should be equally harmonious provided one got far enough away from being in a bad unison: fifths, augmented fifths, and sixths minor and major, ought all to be equally harmonious. This no musician will allow. To account for this von Helmholtz makes the further supposition that the beats occur, not simply between the fundamental or prime tones, but also between the upper partials which usually accompany prime tones. This leads me to say a word about *upper partial tones* and *harmonics*. I believe many musicians use these two terms as synonymous; but they ought to be carefully distinguished. The term harmonics ought to be rigidly reserved to denote higher tones which stand in definite harmonic relations to the fundamental tone. The great mathematician Fourier first showed that any truly periodic function, however complex, could be analyzed out and expressed as the sum of a certain series of periodic functions having frequencies related to that of the fundamental or first member of the series as the simple numbers 2, 3, 4, 5, &c. Thirty years later, G. S. Ohm suggested that the human ear actually performs such an analysis, by virtue of its mechanical structures, upon every complex sound of a periodic character, resolving it into a fundamental tone, the octave of that tone, the twelfth, the double octave, &c. Von Helmholtz, arming himself with a series of tuned resonators, sought to pick up and recognize as members of a Fourier series, the higher harmonics of the tones of various instruments. In his researches he goes over the ground previously traversed by Rameau, Smith, and Young, who had all observed the co-existence, in the tones of musical instruments, of higher partial tones. These higher tones correspond to higher modes of vibration in which the vibratile organ—string, reed, or air-column—subdivides into two, three, four, or more parts. Such parts naturally possess greater frequency of vibration, and their higher tones, when they co-exist along with the lower or fundamental tone are denominated *upper partial tones*, thereby signifying that they are higher in the scale, and that they correspond to vibrations *in parts*. It is to be regretted that Prof. Tyndall, in his lectures on sound, rendered von Helmholtz's *Oberpartialtöne* by the term *overtones*, omitting the most significant half of the word. To avoid all confusion in the use of such a term I shall rather follow Dr. Kœnig in speaking of these as *sounds of subdivision*. And I must protest emphatically against calling these sounds harmonics, for the simple reason that in many cases they are very inharmonious. It is a matter to which I shall recur presently.

Returning to the subject of beats, the question arises, What becomes of the beats when they occur so rapidly that they cease to produce a discontinuous sensation upon the ear? The view which I have to put before you in the name of Dr. Kœnig is that they blend to make a tone of their own. Earlier acousticians have propounded, in accordance with this view, that the *grave harmonic* of Tartini (a sound which corresponds to a frequency of vibration, that is the difference between those of the two tones producing it) is due to this cause. Von Helmholtz has taken a different view, denying that the beats can blend to form a sound, giving reasons presently to be examined. Von Helmholtz considered that he had discovered a new species of combinational tone—namely, one corresponding in frequency to the *sum* of the frequencies of the two tones, whereas that discovered by Tartini (and before him by Sorge) corresponded to their *difference*. Accordingly, he includes under the term of combinational tones the differential tone of Tartini and the summational tone which he considered himself to have discovered. To the existence of such combinational tones he ascribed a very important part in determining the character, harmonious or otherwise, of chords; and to them also he attributes the ability of the ear to discriminate between the degrees of harmoniousness possessed by such intervals (fifths, sixths, &c.) as consist of two tones too widely apart on the scale to give beats of a discontinuous character. He also considers that such combinational tones are chiefly effective in producing beats, the summational tones of the primaries beating with their upper partial tones; and that this is the way in which they make an interval more or less harmonious.

The whole fabric of the theory of harmony, as laid down by von Helmholtz, is thus seen to repose upon the presence or absence of beats; and the beats themselves are in turn made to depend, not upon the mere interval between two notes, but upon the timbres also of those notes, as to what upper partials they contain, and whether those partials can beat with the summational tone of the primaries. It becomes, then, of the utmost importance to ascertain the precise facts about the beats and about the supposed combinational tones. What the numbers of beats are in any given case: whether they do or do not correspond to the alleged differential and summational tones: these are vital to the theory of harmony. Equally vital is it to know what the timbres of sounds are, and whether they can be accurately or adequately represented by the sum of a set of pure harmonics corresponding to the terms of a Fourier series.

In investigating beats and combinational tones, Dr. Kœnig deemed it of the highest importance to work with instruments producing the purest tones; not with harmonium reeds or with polyphonic sirens, the tones of which are avowedly complex in timbre, but with massive steel tuning-forks, the pendular movements of which are of the simplest possible character. Massive tuning-forks properly excited by bowing with a violoncello bow, or, in the case of those of high pitch, by striking them with an ivory mallet, emit tones remarkably free from all sounds of subdivision, and of so truly pendular a character (unless over-excited) that none of the harmonics corresponding to the members of a Fourier series can be detected. No living soul has had a tithe of the experience of Dr. Kœnig in the handling of tuning-forks. Tens of thousands of them have passed through his hands. He is accustomed to tune them himself, making use of the phenomenon of beats to test their accuracy. He has traced out the phenomena of beats through every possible degree of pitch, even beyond the ordinary limits of audibility, with a thoroughness utterly impossible to surpass or to equal. Hence, when he states the results of his experience, it is idle to contest the facts gathered on such a unique basis. The results of Dr. Kœnig's observations on beats are easily stated. He has observed primary beats, as well as beats of secondary and higher orders, from the interference of two simple tones simultaneously sounded.

When two simple tones interfere, the primary beats always belong to one or other of two sets, called an *inferior* and a *superior* set, corresponding respectively in number to the two remainders, positive and negative, to be found by dividing the frequency of the higher tone by that of the lower.

This mode of stating the facts is a little strange to those trained in English modes of expressing arithmetical calculations; but an example or two will make it plain. Let there be as the two primary sounds two low tones having the respective frequencies of 40 vibrations and 74 vibrations. What are the two remainders, positive and negative, which result from dividing the higher number, 74, by the lower number 40? Our English way of stating it is to say that 40 goes into 74 once, and leaves a (positive) remainder of 34 over. But it is equally correct to say that 40 goes into 74 twice all but 6: or that there is a negative remainder of 6. Well, Dr. Kœnig finds that, when these two tuning-forks are tried, the ear can distinguish two sets of beats, one rapid, at 34 per second, and one slow, at 6 per second.

Again, if the forks chosen are of frequencies 100 and 512, we may calculate thus: 100 goes into 512 five times, plus 12; or 100 goes into 512 six times, minus 88. In this actual case the 12 beats belonging to the inferior set would be well heard: the 88 beats belonging to the superior set would probably be almost indistinguishable. As a rule, the inferior beat is heard best when its number is *less* than half the frequency of the lower primary, whilst, when its number is *greater*, the superior beat is then better heard. Dr. Kœnig has never been able to hear any primary beat which did not fall within this rule.

Dr. Kœnig will now illustrate to you the beats, inferior and superior, as produced by these two massive tuning-forks,[1] each weighing about 50 pounds, and each provided with a large resonating cavity consisting of a metal cylinder, about 4 feet long, fitted with an adjustable piston. One of them is tuned to the note $ut_1 = 64$. The other also sounds ut_1; but by sliding down its prongs the adjustable weights of gun-metal, and screwing in the piston of the resonator, its pitch can be raised a whole tone to $re_1 = 72$. Dr. Kœnig excites them with the 'cello bow, first separately that you may hear their individual tones, then together. At once you hear an intolerable beating—the beats coming 8 per second. This

[1] These splendid forks, with their resonators, along with other important pieces of Dr. Kœnig's apparatus, have since been acquired by the Science and Art Department for the Science Collection at South Kensington.

is the inferior beat, corresponding to the positive remainder; the superior beat you cannot hear. Dr. Kœnig will raise the note of the second fork from re_1 to $mi_1 = 80$; and the beats quicken to 16 per second. Raising it to $fa_1 = 85\frac{1}{3}$, and then to $sol_1 = 96$, while the first fork is still kept at ut_1, the beats increase in rapidity, but are fainter in distinctness. If Dr. Kœnig now substitutes for the second fork one tuned to $la_1 = 106\frac{2}{3}$, you may be able to hear two beats, the inferior one rapid and faint at $42\frac{2}{3}$ per second, and the superior one slower, but also faint, at $21\frac{1}{3}$ per second. Still raising the pitch to the true seventh tone $= 112$, the rapid inferior beat has died out, but now you hear the superior strongly at 16 per second. If it is raised once more to $si_1 = 120$ (the seventh of the ordinary scale), and the beats are still stronger and slower at 8 per second. Finally, when we bring the pitch up to the octave $ut_2 = 128$, we find that all beats have disappeared: there is a perfectly smooth consonance. The facts so observed are tabulated for you as follows:—

Table I.

Primary Beats.

Primary Tones.		Ratio.	Inferior Beats.	Superior Beats.
ut_1 64	re_1 72	8 : 9	8	—
ut_1 64	mi_1 80	4 : 5	16	—
ut_1 64	fa_1 $85\frac{1}{3}$	3 : 4	$21\frac{1}{3}$	—
ut_1 64	sol_1 96	2 : 3	32	32
ut_1 64	la_1 $106\frac{2}{3}$	3 : 5	$42\frac{2}{3}$	$21\frac{1}{3}$
ut_1 64	(7) 112	4 : 7	—	16
ut_1 64	si_1 120	8 : 15	—	8
ut_1 64	ut_2 128	1 : 2	—	0

Suppose now, keeping the lower fork unaltered, we raise the pitch of the higher note (taking a new fork that starts at the octave) from ut_2 to sol_2 by gradual steps, we shall find that there begins a new set of primary beats—an inferior set, which are at first slow, then get more rapid and become undistinguishable, but succeeded by another rapid and indistinct, which grow stronger and slower, until, as the pitch rises to sol_2, the frequency of which is exactly three times that of ut_1, all beats again vanish. This range between the octave and the twelfth tone may be called the second "period," to distinguish it from the period from unison to the first octave, which was our first period. Similarly, the range from the twelfth tone to the second octave is the third period, and from thence to the major third above is the fourth period, and so forth. In each period, up to the sixth or seventh of such periods, a set of inferior and a set of superior beats may be observed; and in every case the frequency of the beats corresponds, as I have said, to one or other of the two remainders of the frequencies of the two tones. No beat has ever been observed corresponding to the sum of the frequencies, even when using the slowest forks. None has ever been observed corresponding to the difference of the frequencies, save in the first period; where, of course, the positive remainder is simply the difference of the two numbers.

That you may hear for yourselves the beats belonging to one of the higher periods, Dr. Kœnig will take a pair of forks which will give us some of the superior beats in the fourth period. One of the forks is the great $ut_1 = 64$, as previously used. The other is $mi_3 = 320$; their ratio being 1 : 5. Sounded together they give a pure consonance, but if the smaller one is loaded with small pellets of wax to lower its pitch slightly, and then bow it, at once you hear beats. It was in studying the beats of these higher periods that Dr. Kœnig made the observation that whereas the beats of an imperfect unison are heard as alternate silences and sounds, the beats of the (imperfect) higher periods—twelfth tone, double octave, &c.—consist mainly in variations in the loudness of the lower of the two primary tones; an observation which was independently made by Mr. Bosanquet, of Oxford.

Passing from the beats themselves, I approach the question, What becomes of the beats when they occur too rapidly to produce on the ear a discontinuous sensation? On this matter there have been several conflicting opinions: some holding, with Lagrange and Young, that they blend into a separate tone; others, with von Helmholtz, maintaining that the combinational tones cannot be so explained, and arise from a different cause. Let it be observed that, even if beat-tones exist, it is quite possible for beats and beat-tones to be simultaneously heard. A similar co-existence of a continuous and a discontinuous sensation is afforded by the familiar experiment of producing a tone by pressing a card against the periphery of a rapidly-rotating toothed wheel. There is a certain speed at which the individual impulses begin to blend into a continuous low tone, while yet there are distinguishable the discontinuous impulses; the degree of distinctness of the two co-existing sounds being dependent on the manner in which the card is pressed against the wheel—that is to say, on the nature of the individual impulses themselves. The opponents of the view that beats blend into a tone state plainly enough that, in their opinion, a mere succession of alternate sounds and silences cannot blend into a tone different from that of the beating tone. Having said that the beats cannot blend, they then add that they do not blend; for, say they, the combinational tones are a purely subjective phenomenon. Lastly, they say that even if the beats blend they will not so explain the existence of combinational tones, because the combinational tones have frequencies which do not correspond to the number of the beats.

In the teeth of all these views and opinions, Dr. Kœnig—without dogmatizing as to how or why it is—emphatically affirms that beats do produce *beat-tones*; and he has pursued the matter down to a point that leaves no room for doubting the general truth of the fact. The alleged discrepancy between the frequency of the observed combinational tones and that of the beats disappears when closely scrutinized. Those who count the beats by merely taking the difference between the frequencies of the two primary tones, instead of calculating the two remainders, will assuredly find that their numbers do not agree in pitch with the actual sounds heard. But that is the fault of their miscalculation. Those who use harmonium reeds or polyphonic sirens instead of tuning-forks to produce their primary tones must not expect from such impure sources to reproduce the effects to be obtained from pure tones. And those who say that the beats calculated truly from the two remainders will not account for the summational tones have unfortunately something to unlearn—namely, that, when pure tones are used, under no circumstances is a tone ever heard the frequency of which is the sum of the frequencies of the two primary tones.

The apparatus which Dr. Kœnig has brought over enables him to demonstrate, in a manner audible, I trust, to the whole assembly in this theatre, the existence of the beat-tones. His first illustrations relate to tones of primary beats, some belonging to the inferior, others to the superior set, in the first period.

He takes here the fork $ut_6 = 2048$, five octaves higher than the great ut_1. To excite it, he may either bow it or strike it with an ivory mallet. With it he will take the fork one note higher, $re_6 = 2304$. When he took the same interval with ut_1 and re_1, the number of beats was 8.

The *ut* and *re* of the next octave higher would have given us 16 beats, that of the next 32, that of the next 64, of the fourth octave 128, and that of the fifth 256. But 256 per second is a rapidity far too great for the ear to hear as separate sounds. If there were 256 separate impulses, they would blend to give us the note $ut_3 = 256$. They are not *impulses*, but *beats:* nevertheless, they blend. Dr. Kœnig strikes the ut_6, then the re_6, both shrill sounds when you hear them separately; but when he strikes them in quick succession one after the other, at the moment when the mallet strikes the second fork you hear this clear ut_3 sounding out. I am not going to waste your time in a disputation as to whether the sound you hear is objective or subjective. It is enough that you hear it, pure and unmistakable in pitch. It is the grave harmonic; and the number 256, which is its frequency, corresponds to the positive remainder when you divide 2304 by 2048.

Now let me give you a beat-tone belonging to the superior set: it also will be a grave harmonic, if you so please to call it; but its frequency will correspond neither to the difference nor to the sum of the frequencies of the two primary tones. Dr. Kœnig takes $ut_6 = 2048$ as previously, and with it $si_8 = 3840$. Let us calculate what the superior beats ought to be. 2048 goes into 3840 twice, less 256. Then, 256 being the negative remainder, we ought to hear from these two forks the beat-tone of 256 vibrations, which is ut_3, the same note as in our last experiment. He strikes the forks, and you hear the result. The beat-tone, which is neither a differential tone nor a summational tone, corresponds to the calculated number of beats.

If I take $ut_6 = 2048$ and $sol_6 = 3072$, the two remainders both come out at 1024, which is ut_5. Dr. Kœnig will first sound ut_5 itself, separately, on an ut_5 fork, that you may know what sound to listen for. Its sound has died away; and now he strikes ut_6 and sol_6, when at once you hear ut_5 ringing out. That sound which you all heard corresponds to the calculated number of beats. That is enough for my present purpose.

The next illustration is a little more complex. I select a case in which the beat-tones corresponding to the inferior and the superior beats will both be present. We shall have four tones altogether—two primary tones and two beat-tones. The forks I select are $ut_6 = 2048$, as before, and a fork which is tuned to vibrate exactly 11 times as rapidly as ut_3—it is the 11th harmonic of that note, but does not correspond precisely to any note of the diatonic scale. It has 2816 vibrations, and is related to ut_6 as 11 : 8. The two remainders will now be 768 and 1280, which are the respective frequencies of sol_4 and mi_5. Dr. Kœnig will first sound those notes on two other forks, that you may know beforehand what to listen for. Now, on striking the two shrill forks in rapid succession, the *two* beat-tones are heard.

If I select, instead of the 11th harmonic, the 13th harmonic of ut_3, vibrating 3328 times in the second, to be sounded along with ut_6, the same two beat-tones will be produced as in the preceding case; but $mi_5 = 1280$ is now the inferior one, corresponding to the positive remainder, whilst $sol_4 = 768$ is the superior tone, corresponding to the negative remainder. It is certainly a striking corroboration of Dr. Kœnig's view that the beat-tones actually heard in these last two experiments should come out precisely alike, though on the old view, that the combinational tones were simply the summational and differential tones, one would have been led to expect the sounds in the two experiments to be quite different.

One other example I will give you of a beat-tone belonging to the second period. The two primary notes are given by the forks $ut_5 = 1024$ and $re_6 = 2304$. The beat-tone which you hear is $ut_3 = 256$, which corresponds to the positive remainder.

It will be convenient to draw up in tabular form the results just obtained. These may be considered as abbreviations of the much more extended tables drawn up by Dr. Kœnig, which hang upon the walls, and which are to be found in his book, "Quelques Expériences d'Acoustique."

(*To be continued.*)

THE ORIGIN OF THE GREAT LAKES OF NORTH AMERICA.

AT one time glaciers—perhaps in the co-operative society of an ice-sheet—were gravely suspected of having excavated even the great lakes of North America. This, however, is hardly probable. The *a priori* difficulties in the hypothesis are great. Apart from objections which have often been pointed out, the work done would be on so gigantic a scale that a longer period must be assigned to the glacial occupation of the region than seems probable from other considerations. Further, the direct evidence which will presently be noticed seems conclusive against the hypothesis; but it may be affirmed with better reason that ice has indirectly aided in the process, though to what extent we can, as yet, hardly venture to say.

During the last few years numerous observations have been made, both in Canada and in the United States, upon the configuration of the lake beds, and the elevation of their ancient margins. To some of these Dr. Wright refers in his volume on "The Ice Age in North America," and Prof. J. W. Spencer (who has been engaged on this subject for several years) brings them into a focus in a paper recently published in the Quarterly Journal of the Geological Society of London.[1]

At first sight the great lakes, from Superior to Ontario, are suggestive of glacial excavation. They seem to occupy true rock basins. Superior discharges into Huron over the ledges—once a "portage"—of Sault Ste. Marie. Huron as it were, leaks into Erie, the fall between the two sheets of water being only nine feet. Erie flows towards Ontario over the rocky rapids and the final precipice of Niagara; and the St. Lawrence, after leaving Ontario, gives frequent evidence of a rocky bed, the level of which is considerably above that of the bottom of the lake, for the depth of this near its eastern end is more than seven hundred feet. But more careful investigation of the lakes has shown that in these apparently perfect basins (as is sometimes discovered in household affairs) hidden cracks exist, which, under different physical conditions, would have let the water run out. This indeed is not the whole story; another agency must be presently mentioned; but that these apparent basins once had

[1] Vol. xlvi. p. 523 (read April 16, 1890).

outlets, by which they would have been drained, at any rate partially, seems beyond question.

The following is a brief statement of the results of sounding in the water and boring on the land. The surface of Lake Superior is 630 feet above sea-level, the deepest part of its bed 375 feet below that datum plane. The fall from the shore line is generally rather rapid; a large part of the basin is more than 300 feet deep, and a considerable area is below 600 feet. The original outlet, according to Dr. Wright, was on the southern side; and by this, in pre-glacial times, the drainage was discharged towards the Mississippi. But, apparently, the information in regard to the ancient valley-system of the Lake Superior area is less complete than in the case of the other lakes.

The Huron-Michigan basin at once arrests attention by its extraordinary outline. Michigan is a gigantic backwater without inclosing hills at its southern or upper end. Huron proper is almost divided from Georgian Bay by the Indian Peninsula and a chain of rocky islands, of which Manitoulin Island is the chief. All this is far more suggestive of submergence than of any other mode of formation. Closer study has confirmed first impressions. Michigan really consists of two basins, divided by a plateau submerged at a maximum depth of 342 feet; the northern and larger basin sinks to a depth of 864 feet, the southern one only descends to 576 feet. Hence, if the level of the water were lowered by 350 feet, Michigan would be divided into two lakes.

Of these, the former must have drained into the northwest end of Lake Huron. It is true that the deepest soundings at the present outlet do not exceed 252 feet, but near this a fjord-like channel has been traced in the shallower part, trending northward, with a depth of 612 feet, and there are indications of other buried channels. Thus there can be little doubt that in pre-glacial times the northern basin of Michigan communicated, as the lake still does, with that of Lake Huron. But as to the outlet of the southern basin there is some dispute. Prof. Spencer, however, states that a buried channel has now been traced along the valley of the Grand River, across the peninsula of Michigan to Saginaw Bay on Lake Huron. Its exact depth has not been ascertained, but it has been pierced in several places to depths of from 100 to 200 feet below the level of the lake, and in one case the drift was found to extend 500 feet below the surface of the ground, and 350 below that of Lake Huron.

Next as to the drainage of this lake. Submerged channels resembling river valleys have been traced along its bed. One is a prolongation, in a north-easterly direction, of that which has just been mentioned. Another runs to join it from the south—that is, in the opposite direction to that of the present flow of the water; and a third is a continuation of the channel which drained the northern basin of Michigan. These three ultimately come together, and the united valley rounds Cabot's Head, and makes for the southern end of Georgian Bay, keeping near its south-western side. Here also an ancient outlet has been found. Across the low flat land separating the waters of Georgian Bay from Lake Simcoe a buried channel has been struck in borings, at various depths—in one case 280 feet—below the surface of the latter. Between this and Lake Ontario, well-borings indicate that the drift is very deep, and that it conceals an ancient channel, which entered Lake Ontario some thirty miles west of Toronto. Lake Erie, which is generally less than 84 feet deep, also exhibits a buried system of ramifying valleys, and the line of discharge into Ontario was not over the lip of Niagara but by a deep valley, now choked with drift, which can be traced several miles to the west of the present course of the St. Lawrence. In Ontario, also, a channel has been found, the greatest depth of which is over 700 feet below the surface of the lake. This runs near the southern shore, and receives other valleys from this direction.

The conclusion to which these investigations point is that in pre-glacial times the great lakes did not yet exist, but their site formed part of a system of river valleys, which ultimately coalesced in one main channel, now concealed beneath the waters of the eastern part of Ontario. Of these valleys, the one was cut off from the united system of the other tributaries at Detroit, and the head waters of these were parted by the plateau now buried beneath Lake Michigan. Some, indeed, have contended that the water of these rivers passed from the Ontario region towards the Hudson, but Prof. Spencer considers that they were even then tributary to the St. Lawrence.

But it would not suffice to block these channels with glacial drift. Parts of Lake Superior, the southern basin of Michigan, a little of Huron, and the eastern end of Ontario are beneath the sea-level: the last as much as 491 feet below it. We must assume in addition a considerable downward movement of the whole area, otherwise these valleys could never have emptied themselves into the sea. To drain the valley occupied by Ontario would require, at the least, an elevation of more than 700 feet; Southern Michigan, of not much less, perhaps of more. This hypothesis, however, presents no real difficulty, for it can be proved that many regions have been affected by movements, both upwards and downwards, in glacial or post-glacial times. The coast of Norway and many parts of northern America have been affected by a great downward movement—amounting not seldom to at least a thousand feet, and sometimes even as much as a thousand yards. This, again, after the ice had melted away and the main physical features of the district were sculptured, was followed by one in the contrary direction, which may be occasionally measured by some hundreds of feet; as, for example, at the beaches of Novaya Zembla, the terraces of the Varanger Fjord, and of many another inlet in Norway. Of this movement also there is proof on the Fraser and other rivers in America.

But to convert Lake Ontario into a river valley it would not be enough to give a general uplift and clear away the dams of glacial drift. Differential movements of the earth's crust are required. That these have sometimes occurred has been long since proved, in the case of Norway. Now, careful observations, by Prof. Spencer and others, show the reasonableness of the hypothesis in the district of the great lakes. Around their shores are old terraces, which extend in some cases to a height of 1700 feet above the present water-level, and are indicative, in Prof. Spencer's opinion, of a depression to that amount. A series of careful measurements undertaken on different terraces and around more than one American lake prove that these terraces do not correspond with the existing contour lines, but have been affected by a differential uplift, amounting in one case to as much as 4 feet per mile.

Hence, it follows that the great North American lakes are of comparatively modern date, and are nothing more than a great system of river valleys, which have been converted into a chain of huge lakes, partly by the blockage of old channels, partly by differential movements of the earth's crust. If this view be established, and the evidence in its favour (which finds much support from other regions) appears very strong, it will help in elucidating several important questions, bearing on not only the history of the Glacial epoch and the exact mode of the accumulation of the *débris*, but also on the cause of the movements of a crust which is asserted by physicists to be rigid. But into these questions, fascinating as they are, want of space precludes us from inquiring on the present occasion.

T. G. BONNEY.

THE ISOLATION OF HYDRAZINE, $\begin{array}{c}NH_2\\ |\\ NH_2\end{array}$.

IN the June of 1887, Prof. Curtius, of the University of Erlangen, announced, in the *Berichte* of the Berlin Chemical Society, the important fact that he had succeeded in preparing the hydride of nitrogen, $\begin{array}{c}NH_2\\ |\\ NH_2\end{array}$, di-amidogen or hydrazine, and an account of his preliminary experiments was given in NATURE (vol. xxxvi. p. 185). Since that time several further contributions to the history of the base and its salts have been published by Drs. Curtius and Jay (see NATURE, vol. xxxix. p. 377, and vol. xli. p. 547), and the work is now completed by the publication, in the current number of the *Journal für praktische Chemie*, by Drs. Curtius and Schulz, of full details of the perfected methods of preparation of the base and its most important salts, together with the results of determinations of its vapour density and of its molecular weight when dissolved in water.

It will doubtless be remembered that free hydrazine was supposed by Prof. Curtius to be a gas, possessing such an exceedingly powerful affinity for water that it was found almost impossible to isolate it from its hydrate. This difficulty has since to a large extent been overcome, and the nature of the gas itself more certainly ascertained. The hydrate is a very definite compound of the composition $N_2H_4 . H_2O$, and it serves as the best starting-point for the preparation both of the free gaseous hydrazine itself and of the salts of the base.

Preparation of Hydrazine Hydrate.

Hydrazine hydrate is best prepared by distilling the sulphate, $N_2H_4 . H_2SO_4$, with alkalies. Hydrazine sulphate is a beautifully crystalline salt consisting of colourless rhombic tables, the macropinacoid being the most fully developed face. It is obtained most readily by the method of Curtius and Jay from triazoacetic acid.

The perfected method of preparing hydrazine hydrate from these crystals of the sulphate is as follows:—About one hundred grams of pure caustic potash are dissolved in 250 grams of water. After cooling, a hundred grams of the finely powdered crystals of the sulphate are added, and the mixture subjected to distillation. Owing to the tremendously active properties of hydrazine, the distillation apparatus requires to be constructed throughout of pure silver. The form employed by Prof. Curtius consists of a silver flask of about a litre capacity, which can be screwed in a gas-tight manner to the silver condenser. The connecting-tube between the flask and the condenser is bent into a double U shape, so that particles cannot possibly be projected from the flask into the condenser; a thermometer is inserted in the limb of the U nearest the condenser. The flask is protected from the flame by an asbestos cushion. Cork and india-rubber connections must be rigorously excluded, as hydrazine most energetically attacks them. When the powdered sulphate is added to the strong potash solution in the flask, considerable heat is generated and the thermometer rapidly rises. Heat is then carefully applied, and liquid begins to distil. As soon as the thermometer indicates 119° C., the boiling-point of hydrazine hydrate, the receiver is changed. It is then found that the temperature remains constant at 119° until almost the last drop, the liquid distilling at this temperature being almost pure $N_2H_4 . H_2O$. The distillate collected before the thermometer reached 119°, generally amounting to about 250 c.c., should then be fractioned. It is a most curious fact that, although the boiling-points of water and hydrazine hydrate are so close together, only very small quantities of the latter are carried over by steam. More than two-thirds of the 250 c.c. pass over on redistillation before the mercury rises above 100°. Between 100° and 106° a distillate is obtained which does not contain more than 1 per cent. of hydrazine. The 106°–117° fraction contains still only about 11 per cent., while that passing over between 117° and 119° contains 60–62·5 per cent. of hydrazine. The liquid obtained in the first distillation, while the thermometer indicated 119°, contains 64 per cent. of the free base, the theoretical quantity for the formula $N_2H_4 . H_2O$. From one hundred grams of hydrazine sulphate 36 grams of the pure hydrate are obtained in a careful experiment.

As regards the analysis of the hydrate, the amount of base, N_2H_4, may be determined by means of standard sulphuric acid, all the usual indicators except phenol phthalein being available. The nitrogen and hydrogen may be estimated by combustion with copper oxide, and the nitrogen also by reduction of platinum chloride, the whole of the nitrogen being evolved in the free state in accordance with the equation

$$N_2H_4 . H_2O + 2PtCl_4 = 2PtCl_2 + 4HCl + H_2O + N_2.$$

Molecular Composition of Hydrazine Hydrate.

The vapour density of the compound has been determined by Hofmann's method in the Torricellian vacuum, using a jacket of steam. The molecular weight corresponding to the formula $N_2H_4 . H_2O$ is 50. The numbers obtained from three such density determinations were 48·79, 51·67, and 49·48, showing that the simple formula $N_2H_4 . H_2O$ expresses in all probability the molecular condition. When vapour density determinations at ordinary pressure by Victor Meyer's method are carried out, some rather surprising results are obtained. At the temperature of boiling aniline (183°) the numbers 28·25 and 23·52 were obtained, about half those at 100° *in vacuo*; it appears probable, therefore, that at this temperature and under ordinary pressure complete dissociation into N_2H_4 and H_2O occurs, the molecules of the hydrazine existing side by side with those of water vapour without combination. At higher temperatures the molecular weight appears to increase again, a phenomenon which requires further investigation.

The molecular weight of the hydrate dissolved in water has also been determined by Raoult's method, by noticing the lowering of the freezing-point of water brought about by dissolving a small quantity of the hydrate in it. The numbers obtained from three experiments were 69·73, 70·71, and 71·25, corresponding almost exactly to a hydrate of the formula $N_2H_4 . 2H_2O$.

It appears, therefore, from the above experimental results, that the vaporized hydrate posesses the composition $N_2H_4 . H_2O$. At 183° these molecules appear to dissociate into free hydrazine and water vapour. When the hydrate dissolves in water, it takes up another molecule of water, becoming $N_2H_4 . 2H_2O$.

Properties of Hydrazine Hydrate.

Hydrazine hydrate is a colourless, highly-refractive, but not very mobile, liquid, which fumes when brought into the air. In closed vessels it may be preserved unaltered for any length of time. Its odour is quite different from that of ammonia, and is indeed comparatively weak compared with that of free gaseous hydrazine. It tastes like alkalies, and leaves on the tongue a burning sensation. It possesses strongly corrosive properties, at once destroying cork or caoutchouc. The boiling liquid rapidly attacks glass. It is hygroscopic, and also extracts carbon dioxide from the atmosphere. It mixes with water and alcohol in all proportions, but not with ether, chloroform, or benzene. It solidifies when surrounded by a mixture of solid carbon dioxide and ether to a mass of leaf-like crystals, which again liquefy from some reason or other below −40°. Although hygroscopic, when a drop of the liquid is allowed to fall into a cylinder of water, it remains for a long time at the bottom without mixing.

The specific gravity of the pure liquid of boiling-point 118°·5 (corr.) is 1·0305 at 21°.

A peculiar phenomenon is noticed during the distillation of hydrazine hydrate mixed with water. When a certain stage of concentration is reached, the drops falling from the end of the condenser into the glass receiver before dissolving take the form of extended filaments, often fine threads, which do not adhere to the walls of the receiver. The liquid hydrate reacts very strongly alkaline to vegetable colouring matters. Its reducing properties, as mentioned in the earlier notes in NATURE before referred to, are extraordinarily marked, most of the ordinary salt solutions of silver, gold, platinum, ferric iron, and cupric copper being reduced, and in the case of silver beautiful metallic mirrors deposited. Mercuric oxide reacts with it so energetically as to bring about an immediate explosion.

Free Gaseous Hydrazine.

Owing to the extreme affinity of hydrazine for water to form the hydrate, the free base is only liberated from the latter compound with the greatest difficulty. When the liquid hydrate is dropped upon barium oxide in a fractionating flask, the mass becomes very hot; but on distilling, almost the total quantity of hydrazine hydrate distils over unchanged. By repeated distillation over recently ignited baryta, a portion of the water in the hydrate is certainly retained, however, and the distillate fumes more strongly in the air. When the mixture of hydrate and baryta is heated in a sealed tube to 100° C. the reaction goes much further; and when the temperature is increased to 170°, at which temperature under ordinary pressure hydrazine hydrate is dissociated into N_2H_4 and H_2O, the decomposition is complete, the tube containing barium hydrate and gaseous hydrazine at high pressure. When the end of the tube is softened at the blowpipe, a tremendous rush of the free gas occurs, forming as it escapes a long rod-like white cloud with the moisture of the air, and rendering the atmosphere almost unbearable by its fearfully penetrating odour, compared with which that of the liquid hydrate is extremely weak. Owing to the difficulty of collecting and preserving such an active gas, which reminds one irresistibly of fluorine, Prof. Curtius has not been able to experiment further with it.

Action of Halogens and Halogen Acids upon Hydrazine Hydrate.

The halogen salts of hydrazine have been examined in great detail, and present some most interesting phenomena, throwing considerable light upon the constitution of the base.

Two kinds of salts are found capable of existing—mono-salts of the type $N_2H_4 . HR$, where R represents a halogen element, and di-salts of the type $N_2H_4 . 2HR$.

When the hydrate diluted with water is mixed with hydrofluoric acid, the dihydrofluoride, $N_2H_4 . 2HF$, is obtained in crystals belonging to the regular system melting at 105°. This difluoride appears to sublime unchanged. It may also be obtained by adding hydrofluoric acid to the alcoholic solution of the hydrate, and then precipitating with ether.

The dihydrochloride, $N_2H_4 . 2HCl$, is similarly obtained when hydrazine hydrate is evaporated with hydrochloric acid, or by action of hydrochloric acid upon the alcoholic solution of the hydrate. It is also formed when gaseous chlorine is led into a flask containing hydrazine hydrate; after a few minutes' passage of the gas, the separation of beautiful octahedrons begins, and bubbles of nitrogen escape. The reaction is as follows:—

$$3(N_2H_4 . H_2O) + 2Cl_2 = 2(N_2H_4 . 2HCl) + 3H_2O + N_2.$$

It is interesting to note that this same chloride was obtained by Curtius and Jay by boiling a compound which they prepared, termed benzalazine, $N_2(CH . C_6H_5)_2$, with hydrochloric acid—

$$N_2(CH . C_6H_5)_2 + 2H_2O + 2HCl = N_2H_4 . 2HCl + 2C_6H_5CHO.$$

The monohydrochloride, $N_2H_4 . HCl$, is obtained in long needles by heating the dihydrochloride to 140°. Prof Curtius recommends heating the dihydrochloride in an apparatus heated by vapour of xylene, until no further loss of weight occurs.

The dihydrobromide, $N_2H_4 . 2HBr$, may be prepared by direct evaporation of a mixture of hydrazine hydrate and hydrobromic acid; but if an alcoholic solution of the hydrate is employed, curiously enough the monohydrobromide separates on the addition of ether. If the pure hydrate is added to excess of liquid bromine, the substance decomposes completely with liberation of nitrogen and hydrobromic acid gases, nothing but the excess of bromine remaining. But if the bromine is allowed to act upon the hydrate suspended in chloroform, the monohydrobromide separates as a white mass of crystals, nitrogen being also evolved.

$$5(N_2H_4 . H_2O) + 2Br_2 = 4(N_2H_4 . HBr) + 5H_2O + N_2.$$

Recrystallized from alcohol, the mono-salt may be obtained in large prisms.

The dihydriodide, $N_2H_4 . 2HI$, is only obtainable by one method, the decomposition of the benzalazine above mentioned with fuming hydriodic acid. It is singular that none of the methods applicable to the fluoride, chloride, and bromide yield it. When tincture of iodine is added to a dilute alcoholic solution of hydrazine hydrate, the colour disappears completely, in accordance with the quantitative reaction symbolized by the following equation:—

$$5(N_2H_4 . H_2O) + 2I_2 = 4(N_2H_4 . HI) + 5H_2O + N_2.$$

Nitrogen is evolved, and if the addition of iodine is continued until a permanent coloration is afforded, colourless prismatic crystals of the monohydriodide are obtained on evaporation. These crystals melt at 127°, and in doing so detonate violently. The reaction of hydrazine with iodine may be used volumetrically to estimate the amount of the base in a solution.

In addition to the above iodides, a third, of the composition $N_6H_{12} . 2HI$, or $3N_2H_4 . 2HI$, is obtained in well-defined crystals when an insufficient amount of iodine to form the monohydriodide is used.

Finally, a series of molecular weight determinations of these halogen salts by Raoult's method, using water as the solvent, have been made, with most interesting results. The mono-salts all give numbers agreeing with the molecular weight $\frac{N_2H_4 . HR}{2}$, showing that in solution they are dissociated into hydrazine N_2H_4, and the acid HR. The tri-iodide yields numbers corresponding to $\frac{3N_2H_4 . 2HI}{5}$, a fact which appears to indicate a dissociation into three molecules of N_2H_4, and two molecules of HI. Similarly the sulphate gives values corresponding to $\frac{N_2H_4 . H_2SO_4}{2}$, pointing to its dissociation into separate molecules of N_2H_4 and H_2SO_4. The di-salts afford results indicating a molecular weight $\frac{N_2H_4 . 2HR}{4}$, as if there were a dissociation of the kind $\begin{matrix} NH_3 \mid I \\ NH_3 \mid I \end{matrix}$. The fluoride appears to behave abnormally, yielding numbers corresponding to $\frac{N_2H_4 . 2HF}{2}$, as if the hydrofluoric acid liberated in the dissociation possessed the constitution H_2F_2.

A. E. TUTTON.

THE ALPINE FLORA: WITH A SUGGESTION AS TO THE ORIGIN OF BLUE IN FLOWERS.

WHEN in Colorado, I made notes on the plants of the Rocky Mountains, and collected some memoranda from various sources bearing upon alpine floras. Recently, when going over my records to ascertain as far as possible the definite results of environment on high alpine vegetation, I arrived at some conclusions which seemed to throw light on what had puzzled me before. These are at present more or less hypothetical, but I hope to work out the subject in more detail later on, so as to ascertain more clearly whether they will satisfy all the necessities of the case.

High alpine plants differ from those of the lowlands in one or more ways. They may be dwarfed, the leaves more divided or more thickly clothed with hairs, and the flowers are more often blue or pink. For the present, the dwarfing and the colour of the flowers need only be considered. Dwarfing may be—doubtless often is—the direct result of environment, as lack of nourishment. The dwarfed trees grown by the Japanese artificially in small pots are well known.

If this were the only cause of dwarfing, the alpine flora would present clear evidence for the transmission of acquired characters, as the character has undoubtedly become a *specific* one in several mountain plants. Thus, oaks are normally trees: the Rocky Mountain oak, *Quercus undulata*, is usually a shrub. The genus *Phlox* contains fine herbaceous plants, but *P. cæspitosa*, which I have gathered at about 12,000 feet on the Sangre de Cristo Range in Colorado, is so dwarfed as to be called (with other dwarfs growing beside it) "flowering moss." It appears, however, that natural selection may come into play, the low stature of these plants benefiting them in three ways :—

(1) They may escape the violence of the high winds which prevail at those altitudes; taller plants being broken off before the seed matures.

(2) They may obtain some additional warmth from their close proximity to the ground and partial shelter.

(3) The short summer of the mountain-tops necessitates very rapid development, and requires every energy to be thrown into the essential function of producing flowers and seed, leaving nothing to spare for the production of branched stems and diffuse foliage. In short, the plants are obliged to develop as *katabolically* as possible, and those which fail in the race are ruthlessly cut off by the autumn storms.

The evidence at hand tends to show the reality of this rapid development and the necessity for it. Every alpine traveller knows how rapid is the bursting into bloom of the plants but lately covered by snow and ice. Their impatience, if one may so call it, is astonishing, some plants will begin to develop under the snow. Then the flowers that are produced are very brilliant, lasting but for a short season (like some alpine Lepidoptera), and especially is it to be noted that they are nearly always *large in proportion to the size of the plant*. That is, the plants have dwarfed, but the flowers *have not become dwarfed at the same time*. This were strange, if bad nourishment were the only factor: in the light of the facts considered above it is exactly what one might expect.

The intense blue of some high alpine flowers is most noticeable, and the large number of blue flowers is equally remarkable. I never saw anything equalling in *blueness* the *Omphalodes nana* var. *aretioides* of the Colorado mountains above timber-line. The brilliancy of these flowers is almost dazzling. The large and beautiful blue flowers of species of *Gentiana*, *Polemonium*, &c., are conspicuous on high mountains. Next to the blues come the pinks. I have shown in the *Bulletin of the Torrey Botanical Club* how species of *Castilleia*, which are scarlet or yellow at lower altitudes, become crimson-bracted as they ascend. Many other examples could be given.

I have found no one to dispute the reality of this change of colour, at least in many groups of plants. The cause of it seemed much more obscure. It is generally agreed that, developmentally, reds come after yellows, crimson follows red, and blue crimson. Further, it is supposed that this series of colours is the result of different degrees of pigmental complexity, perhaps of the nature of, or similar to, various degrees of oxidation. Katabolism, strong metabolism, produces the higher colours—the crimsons, the blues. Moisture, slow development, great growth, with an expansion of the parts—these are favourable to the yellows, and, in a less degree, to the reds; of course the green, the primitive chlorophyll, especially.

May not all this, therefore, be correlated with the dwarfing? Strong metabolism is necessary; every energy must be thrown into the inflorescence; and, as a side-result, we get the crimsons and blues of mountain flowers.

It may be, even, that all, or nearly all, blue flowers were produced in this way. Very few of those groups of plants which are never alpine have blue flowers. There will be some exceptions, of course—for instance, I do not know how to account for the blue water-lily—and there are some groups in which a blue flower, however alpine the species, seems to be unproduceable. But even some of the very refractory genera, as *Erysimum* and *Troximon*, do go so far as to produce an occasional purple flower at high altitudes.

If I am right in my suggestions, the need for the selection by bees, made so much of by various authors, no longer exists. My own observations make me very doubtful whether bees do really prefer blue flowers at all, as a general thing—and I can hardly bring myself to believe, though the present hypothesis fall to the ground, that blue in flowers is a result of insect-selection.

T. D. A. COCKERELL.

NOTES.

AN International Scientific Congress will be held in Moscow in 1892. It will be divided into two sections, one of which will deal with zoology, the other with anthropology and ethnography. It is expected that the meetings will be largely attended. According to the *Revue Scientifique*, there is some talk of excursions to the Caucasus and to Turkestan.

WE learn from *Science* that the United States Coast and Geodetic Survey Office lately received from its sub-office in San Francisco a telegram announcing that an agent of the Alaska Commercial Company had arrived from St. Paul, Alaska, bringing letters from the Coast and Geodetic Survey parties who have been engaged in making explorations and surveys on and near the 141st meridian of longitude (the boundary between Alaska and the British possessions). These two parties were commanded by Messrs. J. E. McGrath and J. H. Turner, assistants of the Coast and Geodetic Survey. The party under Mr. McGrath ascended the Yukon River to the boundary-line, and there made its head-quarters, while that headed by Mr. Turner went up the Porcupine River to the Rampart House (the Hudson Bay Company's trading-post in the vicinity of the boundary), and there camped for the further prosecution of their work. Both parties were at their posts early in the autumn of 1889. The records made by Mr. McGrath's party comprise a set of magnetic and meteorological observations for a year; a set of specimens of sediments obtained from filtering certain measured quantities of the water of the Yukon River, made at regular intervals; certain botanical specimens; and a series of photographs. Mr. McGrath also gathered considerable information from some of the most intelligent of the Indians whom he encountered at Forty-Mile Trading-Post Owing to the stormy weather, Mr. McGrath was unable to obtain a sufficient number of astronomical observations to justify him in returning last autumn; and his party will therefore remain until next spring, and then descend the river, doing what work they can in the cause of science on their way down. Mr. Turner's party were much more favoured by the weather than the other party. They completed the necessary astronomical observations for the determination of the geographical position of their station on the Porcupine River at the boundary-line, also a set of magnetic and meteorological observations, and made a topographic map (on a scale of 1 : 5000) of the river in the vicinity of their camp, and a survey (on a scale of 1 : 200,000) from the boundary to Fort Yukon, a distance of about 100 miles. A small scheme of triangulation was undertaken to "locate" three monuments placed to mark the boundary-line. An exploring expedition was sent during the months of March and April to explore the line northward to the Arctic Ocean. The party visited Herschel Island. During May another trip was made about forty miles to the southward, as far as Salmon Trout River. Mr. Turner reached St. Michael's on August 30, 1890, with his party, too late to catch the steamer going south. The party will winter there, and in the spring carry the triangulation toward the mouth of the Yukon River, until relieved by orders from the Coast and Geodetic Survey Office.

THE next Deutsche Geographentag will be held in Vienna on April 1, 2, and 3.

THE other day, on the occasion of the sixtieth anniversary of the first doctorate of M. de Quatrefages, the anthropologist and zoologist, a small group of his most intimate friends and pupils met at his house and presented him with a very fine copy of an etching of himself, prepared without his having heard anything about the matter. M. de Quatrefages is over eighty years of age; he is in excellent health, and works hard. A few weeks ago he was elected President of the French Geographical Society.

IN St. Petersburg, an Institute for Experimental Medicine has been founded by the liberality of Prince Alexander Petrowitch of Oldenburg. It is intended chiefly for the study of the causes of infectious disease, and methods of prevention and cure. The Prince proposes to invite eminent men of science to make experiments in bacteriology, physiology, chemistry, biology, and the veterinary art. The building, which is being elaborately fitted up, stands in the Lapukins Kaja Street, on the banks of the Neva. Like the Pasteur Institute in Paris, it will have a department for clinical observation.

AT the meeting of the Photographic Society of Great Britain, on December 9, 1890, Mr. W. S. Bird spoke of the work done by the Committee which had been deputed to consider various questions relating to the proposed Photographic Institute. The labours of the Committee had resulted in the drawing up of a large scheme and of a smaller scheme. The larger scheme was a project of the future, but the smaller one was of a more practicable nature, and the Committee had had the advantage of conferring with the Lord Mayor on the subject, who thought that it might be possible to collect a sum which had for its limit £10,000, provided that the project was shown to be of public utility. If this was so, he thought that the photographic community generally should take some steps towards defining practical methods of carrying the scheme forward, and then they could approach the Lord Mayor with this project, and with some promises of financial support. In foreign countries the Government provided the means by which such institutions were founded. In England this was not the case, and he (Mr. Bird) felt that if this movement was to be a success, it must begin at home, and the Photographic Society ought to use what influence it possesses to assist in the work. After some discussion the following resolution was adopted :—"That the project be submitted, in the form of a circular letter, to the different provincial and metropolitan Societies, to elicit the opinion of the photographic public generally upon the scheme now brought forward."

AT the Annual Conference of Principals of University Colleges, held at Bangor, on December 23, the following subjects were discussed :—(1) The University of London: (*a*) the proposed scheme for reconstituting the University; (*b*) local centres at provincial Colleges for the honours examinations of the University. (2) Day Training Colleges: (*a*) relations of the University Colleges in this connection to the Education Department and the Science and Art Department; (*b*) organization necessary to make these relations operative. (3) County Councils: (*a*) relation of County Councils to educational institutions outside the strict county area; (*b*) devotion of local taxation money to purposes of technical instruction. An invitation from University College, London, to meet in London in 1891 was accepted.

AT the meeting of the French Academy on December 8, M. Mascart presented a work by General A. de Tillo on the distribution of atmospheric pressure in the Russian Empire and Asia, from 1836 to 1885. The work consists of an atlas of 69 charts, and a discussion of the monthly and annual values, as well as of the variability of pressure, and the relations existing between the variations of pressure and those of temperature at 136 stations. The highest pressure quoted is 31·63 inches (reduced to sea-level) in December 1877 at Barnaoul, and this is stated to be the highest reading on record. But in the Quarterly Journal of the Royal Meteorological Society for July 1887, Mr. C. Harding quoted, on the authority of Prof. Loomis, a reading of 31·72 inches on December 16, 1877, at Semipatalinsk. In NATURE, vol. xxxv. p. 344, Mr. Blanford quoted the lowest reading on record at any land station, viz. 27·12 (reduced to English standards), which occurred on September 22, 1885, on the coast of Orissa. These readings give a difference of 4·6 inches, probably the maximum range of the barometer ever observed at the earth's surface.

THE weather review accompanying the Pilot Chart issued by the U.S. Hydrographic Office states that very heavy weather prevailed in the North Atlantic during the month of November; westerly gales accompanied by heavy rain, hail, or snow, with tremendous seas, having raged over almost the entire region between Newfoundland and the British Isles, with the exception of a few days. Eight storms reached the ocean from the continent of North America, two of which crossed the British Isles. Six severe storms also originated in mid-ocean, most of which more or less affected the weather in these islands. Very little fog was reported during the month, and only one iceberg. It is proposed to publish with the next Pilot Chart a supplement devoted to the subject of ice in the North Atlantic during the season of 1889–90, which is perhaps the most notable ice season on record.

AT the recent Congress of Americanists at Paris, Dr. Seler showed that the name Anahuac had been applied by mistake to the plateau of Mexico. "Anauac" means "on or near water," and by all ancient writers was used in the sense of coast-land. Anauac Ayotlan was the seaboard of the Pacific; Anauac Xicalanco that of the Atlantic. Motolinia alone used the word differently. He did not, however, apply it to the plateau, but to the whole of New Spain. According to Dr. Seler, this also was a blunder, and was due to the phrase "cem anahuăc," which is used for "the whole world." The original meaning was "the entire land down to the sea-shore."

A CIRCULAR has been issued by the Department of Science and Art, calling the attention of secretaries of science classes and schools, to alterations to be adopted in the "staging" of science drawings, which are to be sent up to South Kensington for examination in April next. This "staging" has a distinct meaning different from that of "elementary," "advanced," or "honours" stages as used in respect of the subjects of science examinations held in May. The secretaries are therefore requested to avoid using the terms "elementary," "advanced," and "honours," in connection with the labelling of the drawings from copies, from measurement, and original designs which may be submitted next April. Such drawings are to be labelled according to stages about which precise instructions are given.

THE utility of the microphone for observation of earth-tremors and noises was soon recognized, and in Italy especially attention has been given to adapting the instrument for this use. We learn from the *Rivista Scientifico-Industriale*, that Signor Baratta, finding some defects in a method of mechanical registration of the motions of a seismo-microphone, which he had devised, has substituted a photographic system with advantage. The device is briefly this:—The telephone wire is connected with a subterranean microphone. Before the telephone-diaphragm (vertical), and connected with its centre by a fine aluminium wire, is a short slip of the same metal, fixed below, and having a curved piece at the top, which rests against a small mirror, movable about a horizontal axis. This mirror reflects the light from a lamp and lens to photographic paper on a rotated drum. The light is momentarily shut off every quarter of an hour, by a shutter arrangement, worked electro-magnetically by the clock-work which moves the drum.

THE French Department of Trade and Industry is issuing, in two large octavo volumes, the popular lectures given in the Trocadéro Palace during the Exhibition, for the benefit of visitors. The first volume has just appeared. The subjects are most varied, and many of the lectures are valuable.

A RECENT microscopical study, by Herr Schultz, of the skin of toads and salamanders, has yielded some interesting results (*Archiv für mikroscop. Anat.*). There are two kinds of glands, mucus and poison glands. The former are numerous over the whole body; while the latter are on the back of body and limbs, and there are groups in the ear-region behind the eye; and, in the salamander, at the angle of the jaw. The mucus glands are spherical, have a clear glassy appearance, and contain mucus cells and mucus; the poison glands, which are in regular strips on the salamander, are oval, much larger, and have a dark granular look, from strongly refractive drops of poison, a good reagent for which is copper-hæmatoxylin. The poisonous elements are from epithelial cells lining the glands. The mucus glands are for moistening the skin, and the liquid has no special smell, nor a bitter or acid taste. The poison glands are of course protective, and the corrosive juice is discharged differently in toads and salamanders, on stimulating electrically; in the latter it is spirted out in a fine jet, sometimes more than a foot in length, whereas in the toad, after longer action of the current, it exudes sparingly in drops. The physiological action of the poison has lately been studied by some Frenchmen. There is no reason, according to Herr Schultz, for supposing that the mucus glands sometimes become poisonous.

THE preliminary copy of the new map of the Chin-Lushai country, prepared for the surveys made during the recent military expeditions, shows, according to an Indian paper, what remarkable progress has been made in filling up the blank spaces which disfigured the old survey sheets. In the expedition of 1871–72 the country for some considerable distance to the south of Manipur was surveyed, and now the operations from the Chittagong side and from Upper Burmah have enabled the British officers to map in the hill tracts between Demagiri and Kan. Fort White, to the north-east, has also served as a base for valuable observations, while on the south-east the Chinbok country has also been explored. During the present winter several survey parties will be sent out, and a year hence the whole mountainous region between Manipur and Arakan will probably have been mapped.

THE wren is generally supposed to be a gentle little bird; yet on occasion it seems capable of displaying anything but an amiable temper. In the current number of the Selborne Society's magazine, Mr. Aubrey Edwards gives from his note-book the following account of what he calls "a disgraceful scene" between two male wrens:—"April 15, 1889.—I have just been watching two golden-crested wrens fighting. They first attracted my attention by getting up from the ground almost under my feet, and engaging again and falling to the ground. Then rising again one chased the other into a yew-tree near, where I had a good close view of them as they challenged each other, ruffling their feathers, shaking their bodies, singing and dancing about with crests erected, the sun shining on the orange-coloured crests—such a pretty sight. After they had been talking big at each other for some minutes, the hen arrived on the scene, and a desperate fight ensued, the two cocks falling to the ground in fierce embrace, rolling over each other occasionally, but for the most part lying still on the ground with their claws buried in each other's feathers for about a minute. The hen was close by them on the ground, moving about and looking very much concerned at the affray. Her pale yellow crest contrasted notably with the rich orange of the males. After getting up, renewing the combat in a currant bush, falling again and struggling on the ground, they rose and had a chase round the yew-trees, the hen following to see the fun, and presently went off and were lost to view."

DURING the past year the question of technical education in Burmah was taken up under the orders of the Government of India. A new set of examination standards was considered; and at the same time a survey was made of the industries practised in Lower Burmah. A provincial Board is at present being constituted to consider the results of the survey, and to advise the Government generally in all matters connected with technical and industrial instruction. A sum of Rs. 10,000 has been allotted in the current year's budget, and it is hoped that the cause of technical education has secured a real and substantial foundation for future progress. Four engineering pupils at the Sibpur College were some time ago in receipt of Burmah scholarships, but the grant of these scholarships has now ceased, and no more engineering students will be sent to Calcutta.

THE Government of Bombay, in concluding a recent resolution on education in the Presidency, remarks that the degree to which private enterprise has expanded under the revised Grant-in-aid Code has exceeded all anticipations. In 1884–85 the expenditure on institutions maintained by the Department was Rs. 8,47,260 out of a total expenditure of Rs. 41,42,734. It is now little more than 8 lakhs out of $56\frac{1}{2}$ lakhs of expenditure. The whole growth of ways and means has thus been left to other agencies than Government. In the same year aided institutions under private management received from provincial revenues under 2 lakhs, and they now receive from that source alone nearly $4\frac{1}{2}$ lakhs. Private enterprise is becoming the chief power in educating the people. Another marked change is the growth of technical education and the introduction of various types of instruction. In 1884–85 the greater part of the expenditure by Government on its own institutions, which aggregated. Rs. 8,47,260, was assigned as follows: nearly 6 lakhs to colegiate and secondary education, and 1¾ lakhs to special education. In the current year Rs. 2,39,479 out of the 8 lakhs spent on Government institutions were devoted to special education. Private enterprise manages special institutions at a cost of Rs. 1,46,261, whereas the expenditure on this head by aided schools in 1884-85 was only Rs. 39,319. There is thus a greater diversity introduced into educational activity as well as into educational agency. Collegiate and secondary education of the ordinary type receive more expenditure than they did, but there is still greater expansion in other directions. The vastly increased employment of Municipal and Local Boards in the management of primary education is another marked feature of recent years. The tendency of education to range itself under diverse forms of instruction, and under a great multiplicity of controlling agencies, renders the task of administration and of apportionment of public funds as grants-in-aid more difficult. It is remarked with satisfaction that complaints against the Grant-in-aid Code are never heard, and that the record of each succeeding year shows increasing attendance at schools and the enlistment of larger private resources in the work of education. "The Governor in Council is satisfied that the Report of public instruction for the year ending March 31, 1890, will be generally regarded as affording proof of the sagacity with which the Department was administered, and new impulses given to it during the administration of His Excellency the late Governor" (Lord Reay).

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by Mr. P. Boulton; a Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Captain Worster; two Common Marmosets (*Hapale jacchus*) from South-east Brazil, deposited.

OUR ASTRONOMICAL COLUMN.

GREENWICH SPECTROSCOPIC OBSERVATIONS.—The results of the spectroscopic and photographic observations made at the Royal Observatory, Greenwich, in the year 1889 have recently been issued. Mr. Maunder examined the spectrum of χ Cygni on June 3, and compared it with the spectrum of hydrogen as given by a vacuum tube, and that of carbon as given by a Bunsen flame. C and F were not present as bright lines. There was some uncertainty about the G hydrogen line, a bright spot being suspected at or near its position in the violet region. D_3 was not seen as a bright line, but there was a brighter part about λ 5823, which may have been "a mere effect of contrast, or a local brightening of the continuous spectrum." It is also recorded that "the close correspondence as to position of the green and blue bands of the hydrocarbon spectrum with two of the bright zones or interspaces of the stellar spectrum was very apparent. No such correspondence was evident in the case of the yellow band." The mean wave-lengths obtained from two sets of measures of the more refrangible edges of Dunér's bands VII. and IX. are 5170 and 4766. On June 17 an observation was made of the spectrum of Uranus. The spectrum was traced from about λ 6200 to about λ 4600. Measures of the positions of two "dark bands," and an "ill-defined bright region which seemed to consist of two diffused bright bands," gave the following mean wave-lengths :—

Object measured.	Mean wave-length.
Darkest line	5419
Bright band	5336
Bright band	5276
Dark line	4866

"Other irregularities in the brightness of the continuous spectrum were suspected on either side of the principal dark line."

Measures of two of the bright lines in the spectrum of R Andromedæ were obtained on October 19. The brightest line was found to have a wave-length 4872, and was probably F, whilst the position of a feeble bright line was determined as λ 5136.

The spectrum of Davidson's comet (*e* 1889) was observed on August 29. It is recorded that "one bright band in the green could be distinctly made out when the slit was opened very widely. It coincided nearly, if not exactly, with the green band of the hydrocarbon spectrum." No measures were made of the wave-length of the bright band.

The other observations contained in this publication refer to the motion of stars, the sun, moon, and planets in the line of sight, and measures of photographs of the sun.

The volume of "Greenwich Observations" for 1888 has also been issued, and is of the usual character.

COMETS ZONA AND SPITALER.—The following elements have been computed for Spitaler's comet :—

T = 1890 October 26·50833 Berlin mean time.

$$\left.\begin{array}{l} \pi = 58^\circ\ 24'\ 28''\!\cdot\!2 \\ \Omega = 45\ \ 7\ 51\cdot 2 \\ \iota = 12\ 51\ 49\cdot 0 \end{array}\right\} \text{Mean Eq. } 1890\cdot 0.$$

$$\phi = 28\ 11\ 26\cdot 6$$

$$\log a = 0\cdot 537532$$

$$\mu = 554''\cdot 2$$

Period = 6·4 years.

Ephemerides for Berlin Midnight.

ZONA'S COMET.

Brightness at discovery = 1.

Zona's comet is therefore still near Triangulum. Spitaler's comet is in Auriga, and not far from Capella.

The sidereal time at 10 p.m. on January 1 is 4h. 45m. 2·5s., and on January 10 is 5h. 20m. 30·1s.

THE LEONID METEORS.—The current number of *Comptes rendus* (December 22) contains a note from Prof. Denza, the Director of the Vatican Observatory, on the observations made in November 1890 under the direction of the Italian Association for the Observation of Luminous Meteors. The results of the observations made at seven stations on November 13-14, 14-15, and 15-16 are tabulated. They show that the number of meteors seen was greater on November 15-16 than on November 14-15, and much greater on these evenings than on November 13-14. In previous years the maximum occurred on November 13 or 14.

The whole of the observations of this year indicate that the Leonids were more frequent than in previous years, hence it is probable that this augmentation will go on until the next shower in 1899.

SPECTROSCOPIC NOTE (D_3).—The Rev. A. L. Cortie, S. J., has brought forward the question, "Has the line D_3 a coincident dark line in the solar spectrum?" From a discussion of available observations, and an examination of some photographs taken by Mr. Higgs with a Rowland grating, it is concluded—

(1) That D_3 has been seen dark in a sun-spot.

(2) That there is a faint dark line in the solar spectrum, at least within two-tenths of a tenth metre from the bright line.

(3) That this line is due to our atmosphere.

(4) That observers are disagreed as to whether the dark and bright lines coincide in position. (*Monthly Notices*, November 1890.)

AMERICAN BLAST-FURNACE WORK.

THE history of the gradual development of blast-furnace working in America, culminating in the production of 2500 tons of pig-iron in the short space of one week, with an expenditure of only 16·8 cwt. of coke per ton of iron, is interesting, especially if compared with ours, where the largest make has not exceeded 1000 tons, with an expenditure of about 1 ton of coke. It is difficult to find satisfactory reasons for this great difference, and the members of the Iron and Steel Institute may well have been astonished at the results laid before them.

It is stated that the first good results were obtained by breaking away from the traditional practice of regulating the quantity of blast or air by the pressure-gauge, and noting instead the number of revolutions made by the blowing engine; probably it would have been better still if some means had been devised of registering the flow of waste gas issuing from the furnace-mouth.

The new era in the manufacture began in 1880, and is divided into three periods:—(1) Old practice—air supply limited, slow driving. (2) Air in excess, excessive driving, attended with a greater output of iron, but increased consumption of coke. (3) Moderate supply of air, rapid driving, great output of iron with decreased consumption of coke. The best results were obtained with air at a pressure of 9 pounds heated to 1100°, blown in at the rate of 25,000 cubic feet per minute, furnace 18,200 cubic feet capacity; a greater quantity, 30,000 cubic feet, proving too much, whilst with less the make of iron diminished. This furnace produced 10,035 tons of iron in one month, with an expenditure of 1834 pounds of coke; the average ratio of CO to CO_2 being 40 per cent. as against about 48 to 50 in this country. Altogether, the volume of air was increased from 16,000 cubic feet "old practice," to 25,000 per minute with improved results. Ultimately it is probable that 300,000 tons of iron may be produced in three years without repairs.

Some of our most prominent metallurgists took part in the discussion on Mr. Gayley's report, and it soon became evident that some long-cherished ideas and formulæ were open to question. One eminent authority was of opinion, however, that on the whole the utilization of fuel, as shown by analysis, was in favour of English practice; although the actual quantity of fuel burnt to CO_2 was 5·97 as against 4·99 cwt. in Pittsburg, accounting for the difference by pointing out the variations in the appropriation of the heat-units or calories under the various items. It was also remarked that the Pittsburg ore was much richer in iron than the English, the latter fusing 28 cwt. of slag as against 10·71 in the former. The loss of heat due to radiation, &c., and in the waste gases, was also less, and these combined causes might be said to account for the remarkable saving.

English metallurgists and engineers were not unanimous in their approval of the new system; such methods might not after all be better than the older and slower processes practised in this country; an expensive array of air-heating stoves, blast engines, boilers, &c., were required, entailing considerable outlay, possibly exceeding the margin of profit. On the other hand, it was contended that the greater output of iron and the saving in fuel, amounting to £24,000 per annum, would more than cover additional expense, and would be sufficient for relining and repairs of the furnace and accessories three or four times over. Fewer furnaces would suffice, and it would be easier and less expensive to manage, say, two furnaces, than four or more. A well-known authority declared in favour of large makes, coupled with rapid driving, but confessed that after all it was not clear where the advantages lay as regards the plant, working, and final results.

The most suitable form of furnace was discussed, but nothing very definite seems to have been said, beyond the general admission that the form facilitating the unchecked free descent of the ores, &c., was most suitable; a large hearth or crucible was also desirable. The equal distribution of the ascending reducing hot gases was not thoroughly discussed, although it is obvious that unequal distribution of the hot gases must correspond to a like varying reduction and heating of the ores, &c., charged. According to Dr. Percy, the equal distribution of the gases, &c., is of the utmost importance, and in his work a furnace is figured, giving the form of furnace most suitable for general uses; he states that, unless the interior parts, from the mouth downwards, are not properly proportioned, the regular production of iron of uniform quality cannot be insured.

It is submitted that the able discussion which has just been summarized, although accounting for a good deal, is still not so satisfactory as might be. The scientific researches on the *rationale* of the chemical reactions occurring in the blast-furnace, may now be termed complete. We can now determine exactly the chemical reactions of the gases passing through, as also the relative distribution of the calories which a given weight of carbon will produce when burnt to carbonic oxide in the furnace. So far, this seems satisfactory; but one pound of carbon, when burnt in the calorimeter, always gives the same number of calories, *i.e.* number of pounds of water heated 1°, "this is all." It is, however, well known that its combustion may be so regulated as to barely suffice for the fusion of a metal like lead; and with the same fuel a temperature may be attained equalling the fusion-point of the softest steel.

Temperature or heat-intensity may play an important part in blast-furnace work. Iron cannot be properly melted below a temperature well above its fusion point, and unless the fuel is burnt under well-understood conditions, *i.e.* very rapidly, it often occurs in practice that fuel is so slowly burnt as to barely suffice for fusion. Fusion is unduly prolonged, and obviously fuel is wasted, for the simple reason that heat-intensity is proportionate to the rate at which it is consumed.

Economical work depends entirely on the difference in temperature betwixt the heating medium and the heated body; and it follows, as the temperature of the furnace flame and gases approximates to that of the metal heated, considerably less heat is absorbed; finally, when the temperature of the metal approximates closely to that of the flame, the heat absorption becomes nearly inappreciable; thus fusion may be unduly prolonged. This final stage may be termed the critical point, sharply dividing the economical use of fuel from the reverse.[1]

The importance of maintaining the temperature at the end of the process of fusion cannot well be over-estimated: a few hundred degrees more or less makes all the difference.[2] Apparently sufficient attention has not been paid to this in blast-furnace work, although it is plain that as regards fusion of the iron and slag, the same law is applicable as when simply fusing iron in ordinary melting-furnaces.

The delivery of large quantities of air at a high pressure through many large openings (technically the *tuyères*), as practised in America, and the consequent rapid consumption of coke, must necessarily raise the heat-intensity (temperature) much above that of furnaces supplied with only a limited quantity of air, and it follows that, in the latter, iron, &c., is fused slowly, thus entailing a greater consumption of coke.

Concurrently with rapid melting, it is self-evident that the furnace drives faster, for it is obvious that the rate of descent of the materials charged is governed by the more or less rapid fusion of iron and the accompanying consumption of fuel. It is pretty generally admitted that rapid driving should be avoided, on the reasonable assumption that time is required for the complete reduction of the ore by the ascending gases. Yet in America only 16·8 cwt. of coke per ton of iron has been consumed in conjunction with rapid driving; but possibly temperature plays an important part throughout the whole smelting process. The law of heat exchanges previously discussed cannot be evaded. We will assume that the temperature at the *tuyères* in one furnace is 500° higher than in another; it follows that the comparatively cool descending materials absorb in a similar ratio, or more plainly a greater percentage of the total heat is utilized in the former than in the latter instance. It is, therefore, not so surprising that the waste gases leave the high temperature furnace at the comparatively low heat of 340°.

It would appear that, on the whole, sufficient attention has not been directed here to the absolute weight or volume of air used per unit of time with its consequent effects, and it may be ques-

[1] "When iron has attained a temperature of 2500°, it will, when exposed to a heat-intensity of 3200°, absorb less than 1/11 of this, and when iron is receiving the last 100 requisite to bring it up to the welding-heat of 3200°, the temperature of the furnace being 3300°, only 1/24 will enter the iron, the remaining 23/24 being wasted. By raising the temperature to 3700°, 1/6 instead of 1/24 will be utilized, thus exhibiting the fact that an addition of temperature of only 1/8 increases the efficiency of the furnace fourfold."—*Prideau.*

[2] Cause of the remarkable saving of fuel effected by hot blast (Percy, "Metallurgy," p. 425). "It is therefore plain that the mere quantity of heat, *i.e.* the number of units of heat evolved can have little to do with the matter. This being admitted, the inevitable conclusion is that calorific intensity must be concerned, and that the temperature of what may be designated the most active part of the furnace must be higher in the case of hot blast than in the case of cold blast."—*Percy.*

tioned whether as a general rule in this country the area of the air or blast-delivery pipes has been correspondingly enlarged in due proportion to the increased air temperature, often over 1000°, now not uncommon since the introduction of the modern brick-heating stoves. Surely with air expanded to nearly four times its normal volume at 60°, the ordinary blast pipes should be correspondingly enlarged, coupled also with a higher blast pressure. Thus it may be, when using highly heated air, the absolute weight of air (oxygen) supplied may not be properly proportioned to the weight of coke charged, greater or less; and if this be true, it is not surprising that many blast-furnace managers have condemned the use of superheated air; it seems just possible that coke may be charged in excess of the air supply, or *vice versâ*. In America they appear, "by dint of sheer practice," to have somehow realized this; they have even gone further, and ascertained that it is quite possible to deliver too much air. It seems, on the whole, that their superior practice may partly, at least, be explained on the probability that heat-intensity—in other words, temperature expressed in C. or F. degrees—plays its part; and that calculations based on heat-units alone, undoubtedly useful and necessary as they are, have only a limited application.

THE ZOOLOGY AND BOTANY OF THE WEST INDIES.[1]

THIS Committee was appointed in 1887, and reappointed in 1888 and 1889.

During the past year chief attention has been directed to the exploration of the island of St. Vincent, and two collectors have been maintained in that island at the expense of Mr. F. Du Cane Godman, who has kindly assisted the Committee in this manner in order that the funds at its disposal may be chiefly applied to the remuneration of contributors, to whom would be referred the large collections in zoology, already amounting in Insecta alone to about 3000 species. The plants have been determined at the Herbarium of the Royal Gardens, Kew, and are nearly completed to date. A separate report on the collections in zoology and botany is given below.

It is proposed by the Committee to accept the services of Mr. R. V. Sherring, F.L.S., to make collections in botany in the island of Grenada during the coming winter. Mr. Sherring is well acquainted with the West Indies, and has already made collections there, and added several new species of ferns to the flora of Jamaica.

Zoology.

Since the last Report of the Committee three collections have been received from Mr. H. H. Smith, the collector sent by Mr. Godman to the island of St. Vincent. These collections include a complete set of the birds already known to inhabit the island, and a few additional species; a small number of reptiles and crustaceans; a large series of spiders; and a great many Insecta; these last amounting, it is thought, to about 3000 species.

In 1889, Colonel Feilden paid a visit to the island of Dominica for the purpose of ascertaining whether the Diablotin (*Œstrelata hæsitata*) has become extinct there, as has been reported by Ober. The account of his expedition that Colonel Feilden has published leaves little doubt that this is the case.

Although Mr. Smith has now been occupied about a year and a half in the exploration of the island of St. Vincent, Mr. Godman has decided, with the concurrence of the Committee, that he shall still continue there, as it is not yet clear that the more inaccessible portions of the island have been sufficiently examined.

Mr. Godman has agreed to give a first set of the zoological specimens obtained by his collector to the National Collection contained in the British Museum, and the Committee is at present endeavouring to find competent zoologists to work out the extensive series of insects and spiders that has been obtained.

Commander Markham, R.N., contributed some specimens in zoology collected by him in the Leeward and Windward Islands of the West Indies, and Captain Hellard, R.E., local secretary to the Committee at St. Lucia, has recently forwarded four boxes of Lepidoptera collected by him in that island.

Botany.

A small collection of plants, numbering 143 specimens, was received from Mr. J. J. Walsh, R.N. This collection included plants from Dominica, St. Martin's, St. Eustatius, St. Kitts, St. Lucia, and Grenada. Most of the plants consisted of common West Indian species, presumably such as would be met with in the more accessible spots in the various places visited.

The remainder of the plants collected by Mr. Ramage at St. Lucia have been determined. Of 84 species sent, 62 have been fully determined. The others include several that are apparently new. They are wholly woody or forest plants, and comprise *Sloanea* sp., *Picramnia* sp., *Xanthoxylum* sp., *Bursera* sp., *Miconia* sp., *Cybianthus* sp., *Lucuma* sp., *Siparuna* sp., *Helosis* sp., *Gymnanthes* sp., and *Cyclanthus* sp. In one or two cases the material is hardly sufficient for satisfactory determination. Two of the above undetermined species have also been collected in Dominica and one in Martinique by earlier collectors.

Three collections have been received from St. Vincent through Mr. Godman, viz. in September 1889, and March and August 1890. The first collection has been determined at Kew by Mr. Rolfe as far as the end of the *Polypetalæ*. Of the 252 numbers (to this point) 47 were duplicates; thus 205 species were represented. All but about 9 of these were fully determined, the great bulk consisting of widely diffused West Indian plants; 128, or more than half, appear to have been recorded from the island before.

The undetermined specimens are *Trattinickia* sp., *Stigmaphyllon* sp., *Trichilia* sp., *Meliosma* sp., *Lysiloma* sp., *Moquilea* sp., a species of *Eugenia* obtained by Hahn in Martinique, and two species, probably of *Pithecolobium*, of which the material was somewhat inadequate. Several of these appear to be new, the first-named being specially interesting, because the genus was hitherto only known from Guiana and Brazil. In addition to this may be mentioned that several species of somewhat restricted distribution in the West Indies, more especially from Martinique and St. Lucia, have also been found in St. Vincent.

The second collection from St. Vincent consisted for the most part of ferns. Mr. J. G. Baker has fully worked out these. They include 133 species and well-marked varieties, three of which are new. The specimens are in excellent state of preservation, and it is probable that we have amongst them nearly all the fern flora of the island, both of the mountains and the lowlands.

As our knowledge of the fern flora of St. Vincent may be now regarded as practically exhaustive, it seems probable that some species hitherto attributed to the island, on the authority of specimens collected by the Rev. Lansdowne Guilding, really belong to other islands. This error has arisen from want of precision in exactly localizing the specimens, a practice the importance of which was hardly recognized at the time they were collected.

The collections received in August last contain three additional species of ferns, making the total number collected by Messrs. Smith 136. The added species are *Dicksonia cicutaria*, Sw., *Davallia aculeata*, Sw., *Cheilanthes radiata*, R. Br. In addition there are 389 numbers of flowering plants, and 3 palms. These will be determined later.

The Committee would again draw particular attention to the botanical and zoological bibliography of the Lesser Antilles prepared under its direction, and published as an appendix to the Report for 1888. This bibliography has been widely distributed in the West Indies and in Europe, and has proved of considerable service in carrying out the objects for which the Committee was appointed.

The Committee recommend their reappointment, and that a grant of £100 be placed at their disposal.

THE HILL ARRIANS OF INDIA.

AT a recent meeting of the Anthropological Society of Bombay, a paper was read by the Rev. A. F. Painter on the Hill Arrians, who live along the slopes of the Western Ghats in the Native State of Travancore, between Quilon in

[1] Third Report of the B.A. Committee, consisting of Prof. Flower (Chairman), Mr. D. Morris (Secretary), Mr. Carruthers, Dr. Sclater, Mr. Thiselton-Dyer, Dr. Sharp, Mr. F. Du Cane Godman, Prof. Newton, Dr Günther, and Colonel Feilden, appointed for the purpose of reporting on the present state of our knowledge of the Zoology and Botany of the West India Islands, and taking steps to investigate ascertained deficiencies in the Fauna and Flora.

the south and the Travancore-Cochin boundary line in the north. They differ considerably from the ordinary hill tribes of India, and Mr. Painter considers them as Dravidian rather than Kolarian. In colour many of them are remarkably fair. The men average 5 feet 6 inches in height. Their features are, as a rule, well formed. The lips are thin and the nose frequently aquiline. Their villages are situated at a height between 2000 and 500 feet above sea-level. The houses are generally built of split bamboo and mud with grass thatching, but wooden houses such as those used by the inhabitants of the plains are not uncommon. They cultivate the surrounding lands with rice and vegetables.

Their religion and social customs differ considerably from other Malayalam-speaking people, more markedly so in places where they have not come under the power of those living in the plains. Thus in Malabar the law of inheritance through the sister's children prevails. Even the Musnud, or throne, is inherited in this way. But among the Arrians, except where they have been brought under the power of the Hindus, inheritance through the father's children prevails. Even where the former law has been forced upon them they evade the consequences by marrying cousins, so that the property remains in the family. They are divided into *illams*, or clans. Members of the same *illam* may not intermarry; men of a superior *illam* may marry a woman of an inferior *illam*, but the reverse may not be done. There appears to be no difficulty about eating together, but only about intermarriage.

Women occupy a much better position among the Arrians than among the Hindus. They are regarded as equals, move about unrestrictedly, and eat with their husbands, especially at feasts. The fact that a woman eats out of a man's plantain leaf is a sign that she is his wife. The marriage tie is considered sacred, and seldom broken. Polygamy is almost unknown. A man married two sisters, and was considered to have disgraced himself, and was shut out from all feasts, &c. Adultery is considered a great crime. Infant marriage is unknown amongst them, but a curious ceremony prevails, copied from the customs of Nairs and Chogans, though differing in several particulars. As soon as a woman attains maturity, relatives and friends are summoned to a feast. The propitious hour having been fixed, the girl is brought in and made to stand on a plank of jackwood (a tree considered sacred by the Arrians); the father's sister then ties the *tali* or thread round the neck, the feast is then partaken of, and the ceremony is considered complete.

The actual marriage ceremony among the Arrians takes place when the woman is seventeen or eighteen years of age. The horoscopes of the different parties are examined, and the day fixed by the astrologer. Invitations are issued, and a *pandal* erected and the bride placed seated inside. The bridegroom is then brought up by his friends, who demand to know who is inside. The reply is such and such Illakar, as the case may be. If the reply is satisfactory they advance inside, and the bride is brought and placed in the centre. The conductor of the ceremonies on the bride's behalf then proclaims in a loud voice, "I am about to give a woman of such an *illam* to a man of such an *illam*." On the bridegroom's behalf a similar announcement is made. And a set of new clothes is presented by the bridegroom to the bride, and afterwards the happy pair eat out of the same vessel or leaf. This is the crowning part of the ceremony. After a feast the bride is conducted by the wedding party in state to the bridegroom's house, where another feast is spread. The wife lives with her husband in his house.

The Arrians bury their dead. Ancestral worship being practised among them, the ceremonies connected with death are the most elaborate and important. Death brings defilement with it, and none in the house may eat until after the funeral. The body having been washed and betel-nut placed in the mouth, a member of the same clan is appointed, who undertakes to act as master of the ceremonies. He first carefully bathes, then takes a new cloth, and from it tears a narrow strip which he fastens upon himself after the fashion of the Brahminical thread. Going to the place selected for the grave he calls upon the earth to give up 6 feet. He then advances backwards and digs with a hoe, removing three hoesful of the earth. Afterwards he may dig facing the grave. This completed, the body is brought forth and laid in it, the head always lying towards the south. The earth having been thrown, he again advances backwards and draws with a knife three lines round the grave, which are supposed to protect it from evil spirits. A cocoa-nut is broken and some paddy is strewn on the top. In addition to this in some hills a light is placed at the head, another at the foot of the grave. The master of the ceremonies again bathes and returns to the house; two sticks tied crossways are taken and rags soaked with oil tied in the ends and lighted. Taking them in his hands he walks in procession round the house three times, followed by the relations of the deceased. The sticks are then placed, one at the head, the other at the foot of the grave.

After the ceremonies at the grave are over, all concerned in them bathe, a clean new cloth is placed in an inner room of the house, and on it the dead man's property, knife, betel-box, topee, &c., are placed. A feast is prepared, plantain leaves are cut into narrow strips, rice, boiled fowl, plantain, fish, toddy, arrack, and parched rice are placed upon the leaves, lights are lighted, the master of the ceremonies then does obeisance to the spirit which is now supposed to be in the house. The door is closed and the spirit is left to feast. After half an hour it is opened and the things taken forth. At the conclusion of the ceremony the whole assembly partake of a feast consisting of flesh, fish, rice, and arrack. As soon as possible an image of the deceased is prepared, which is brought into the house. Twice a year similar offerings are presented; and in times of drought, ravages by wild beasts, or sickness, vows are made, and prayers such as, "O Ancestor, be not angry with us," are offered.

Female ancestors receive equal honours with males. Of what happens to a soul after death they have no certain belief. The doctrine of transmigration is unknown amongst them. Spirits of men and women for whom no offerings have been made are said to wander about working mischief. If a man dies from accident, such as the fall of a tree, or is killed by a man or wild beast, no ceremonies may be performed for him, nor in the event of a woman dying in child-birth. The spirit is said to wander about working mischief. Ancestral worship is the essential part of their religious system. It consists of a yearly feast and offering to the spirit of ancestors similar to that described as made on the eleventh or fifteenth day after death.

Besides worship of ancestors, there is also the worship of evil spirits or demons, which appears to consist in paying "black-mail" to avoid injury, or bribes to inflict injury on others. The chief demon worshipped by them is the goddess of small-pox, cholera, &c., and it is noticeable that in all their religious festivals and ceremonies strong drink plays a very large part.

ANCIENT MOUNDS AT FLOYD, IOWA.[1]

ON the west side of the Cedar River, one half mile east from Floyd, Iowa, are located a group of three ancient mounds. These mounds, instead of being located on the highest eminence in the region, as is most usually the case, are arranged in a slightly curved line, on a high but level space, fifty feet above, and two hundred and twenty yards back from the stream, and midway between two points (from fifty to sixty rods from each) which face the river, and rise from twenty-five to fifty feet above this level space. The ground, between the mounds and the Cedar, has a rather gently sloping surface. At this point the stream makes a bend to the east, and the mounds thus occupy a position on the south side. The north side of the stream is occupied by a steep, and somewhat broken, wooded bank, which affords a limited though beautiful bit of scenery to this place.

This area, as well as the surface of the mounds themselves, was originally possessed by a heavy growth of timber, but which was cleared away more than twenty years ago, and the soil kept under the plough ever since. These mounds are low and circular, and twenty feet distant from each other. The east, or largest mound, is thirty feet in diameter, and was originally two feet high (so reported by Mr. Sharkey, who first cleared, and still owns the tract), although owing to degradation by the plough it now rises only one and a half feet above the surface of the ground surrounding the mound. The two remaining mounds are smaller and lower than the first one. The third mound—there may be some slight doubt expressed regarding its origin, for the reason that in the south portion of it there is embedded a drift boulder, weighing some seven or eight hundred pounds. This, however, may have been placed here by human hands in the long ago, or the mound may have been an intrusion upon the stone. A partial exploration of the two smaller mounds was made, but without discovering anything.

[1] Reprinted from *The American Naturalist*.

In making a thorough exploration of the larger mound, however, the remains of five human bodies were found, the bones, even those of the fingers, toes, &c., being, for the most part, in a good state of preservation. First, a saucer or bowl-shaped excavation has been made, extending down three and three-fourths feet below the surface of the ground around the mound, and the bottom of this macadamized with gravel and fragments of limestone. In the centre of this floor, five bodies were placed in a sitting posture, with the feet drawn under them, and apparently facing the north. First above the bodies was a thin layer of earth; next above this was nine inches of earth and ashes, among which were found two or three small pieces of fine-grained charcoal. Nearly all the remaining four feet of earth had been changed to a red colour by the long continued action of fire.

All the material of the mound, above and around the bodies, had been made so hard that it was with great difficulty that an excavation could be made even with the best of tools. The soil around the bodies had been deeply stained by the decomposition of the flesh. The first (west) body was that of an average-sized woman in middle life. Six inches to the east of this was the skeleton of a babe. To the north, and in close proximity to the babe, were the remains of a large, aged individual, apparently that of a man. To the east and south of the babe were the bodies of two young though adult persons. The bones of the wonan, in their detail of structure, indicated a person of low grade, the evidence of unusual muscular development being strongly marked. The skull of this personage was a wonder to behold, it equalling, if not rivalling in some respects, in inferiority of grade, the famous "Neanderthal skull." The forehead (if forehead it could be called) is very low, lower and more animal-like than in the "Neanderthal" specimen.

This skull is quite small for an adult individual. The inner portions of the brow ridges are slightly prominent.

The distance from the lower portion of the nasal bone to the upper margin of the eye cavities is only four centimetres. A slight portion of this bone has, however, apparently been broken away.

The distance between the eye sockets at a point midway between the upper margin of the eye cavities and the lower portion of the nasal bone is two and three-fourths centimetres. One of the jaws, containing well-preserved teeth, was found. This was rather strong, but the teeth only moderately so. We were at first inclined to consider the strange form of this skull as due to artificial pressure while living, but a critical examination of it revealed the fact that it was normal, *i.e.* not having been artificially deformed. The teeth of the babe were very small, and the skull thick, even for an adult person.

The next skeleton was that of a man nearly six feet in height. The crowns of all the teeth had been very much worn down, some of them even down to the bone of the jaw.

As before stated, the remaining bodies were those of young adult persons, the skull of one of which was small for a full-grown individual. No relics of any description were found with the human remains in this mound. Their burial appeared to be a very ancient one, the limestone fragments in the floor of the excavation being nearly if not all decomposed.

In other mounds opened on the same stream, at Charles City, six miles below, fragments of the same limestone were not infrequently found, but in no case was decomposition visible, except as a thin outer crust, although the human bones, which were usually more or less abundant, were in no case very well preserved, but, on the contrary, often nearly or entirely decomposed. The fine preservation of the remains in the mound at Floyd was due to the method of burial. This being evidenced by the fact that over a small portion of one of the bodies the earth had not been so thoroughly packed, and as a consequence the bones were almost entirely decomposed away, while the other portion of the body over which the soil had been very firmly packed was well preserved. Judging from all the facts gathered, it seems not improbable to suppose that this represented a family burial.

The question has been raised, "How was it that these five persons were all buried here at the same time, their bodies being still in the flesh?" As we have no reason to suppose that these ancient people possessed any means for preserving, for any length of time, in the flesh, the bodies of their dead, it seems plausible to suppose that these individuals were all swept off at about the same time by some pestilence; or else, upon the death of some dignitary of the tribe or people (perhaps represented by the remains of the old man) the other members of the family were sacrificed, similar to the custom which has prevailed among some ancient tribes or races of historic times.

On the same stream, a short distance below this mound, several other mounds occur which promise to yield interesting results, and which we purpose to explore as opportunity offers.

Royal Society, December 11, 1890.—"Determinations of the Heat Capacity and Heat of Fusion of some Substances to test the validity of Person's Absolute Zero." By S. U. Pickering.

Person made determinations with eight substances to show that the temperature at which their heat of fusion became nil, $t - \frac{l}{C - c}$ (t = temperature of fusion, l = heat of fusion at $t°$, C = heat capacity of liquid, c = heat capacity of solid), was $-160°$ in all cases. This he called the absolute zero. His conclusion may for several reasons be questioned, the chief reason being that he determined C and c at any temperature which happened to be most convenient, and the value of these is largely dependent on temperature: they should both refer to the same temperature, and this is, necessarily, $t°$. The author deduces his values for C and c at $t°$ from determinations made at a series of different temperatures. The substances examined were, sulphuric acid and its monohydrate, hydrated calcium nitrate, and naphthalene, and their temperatures of recrystallization were found to be $-369°$, $-177°$, $-234°$, and $-214°$ respectively, thus refuting Person's conclusion. Benzene was also examined, but the heat capacity of the solid was found to be greater than that of the liquid; this is probably due to an incipient fusion occurring below the temperature of true fusion.

December 18, 1890.—"On the Generic Identity of *Sceparnodon* and *Phascolonus*." By R. Lydekker, B.A. Communicated by Prof. W. H. Flower, C.B., F.R.S.

In the year 1872, Sir R. Owen described two imperfect lower jaws of a large extinct Wombat, from the Pleistocene of Queensland, under the name of *Phascolomys* (*Phascolonus*) *gigas*. Subsequently he described certain imperfect upper incisors, from Queensland and South Australia, characterized by their peculiarly flattened and chisel-like shape, under the new generic name *Sceparnodon*.

In cataloguing the fossil Mammalia in the collection of the British Museum, the author was struck by the circumstance that, while the upper incisors of the so-called *Phascolomys gigas* were unknown, there were no cheek-teeth which could be referred to *Sceparnodon*, and it was accordingly concluded that the teeth described as *Sceparnodon* were probably the upper incisors of *Phascolomys gigas*, and on this supposition it was considered that the latter was generically distinct from existing Wombats, and it was accordingly entered as *Phascolonus gigas* in the Museum Catalogue.

The author now described incisors of *Sceparnodon* and lower jaws of *Phascolonus gigas* obtained at Bingera, New South Wales, from the evidence of which it was concluded that we are now justified in definitely regarding the so-called genus *Sceparnodon* as based upon the upper incisors of the gigantic extinct Wombat known as *Phascolonus*.

Geological Society, December 10.—Dr. A. Geikie, F.R.S. President, in the chair.—The following communications were read:—On some water-worn and pebble-worn stones taken from the apron of the Severn Commissioners' weir erected across the river at Holt Fleet about eight miles above Worcester, by Henry John Marten, Engineer to the Severn Commissioners. The weir referred to in the paper was built in 1844 of soft red sandstone, and some of the stones composing the apron of the weir showing signs of decay were removed in 1887. The average quantity of water passing over each square foot of the stones composing the apron has been estimated at about 2000 gallons per minute. A large proportion of the stones had been drilled through and through by the action of the current upon small pebbles lodged in hollows or between the joints of the stone; and the author estimates that, as a result of 43 years of erosion, six of the stones of the apron, which may be taken as a sample, had lost the following amounts respectively: 45, 60, 48, 50, 37, and 58 per cent. In answer to various questions, the author said he believed the action was principally abrasive, as there was only a small proportion of lime in the stone which would be the subject of chemical action. The weir was placed diagonally across the river, and the stones referred to, which were average samples, were taken from the apron at the upper end of the diagonal, where the abrasive effect appeared to be greatest. The pebbles were principally of quartzose description. The rock from which the stones were taken was of a homogeneous character. In the case of stone No. 1, had the action been uniform, the abrasion would represent a loss of nearly one foot three inches from the surface of the stone as originally placed in the apron, and the others in proportion.—On the physical geology of Tennessee and adjoining districts in the United States of America, by Prof. Edward Hull, F.R.S., late Director of the Geological Survey of Ireland. The area described in the paper is occupied by the Unaka or Blue Ridge, which may be regarded as one of the parallel ridges of the Alleghanies, and the prolongation of Prof. J. D. Dana's "Archæan Protaxis." It runs in a general south-westerly direction, and attains an elevation of 6760 feet. At its base, and to the north-west of it, is the Valley of East Tennessee, about 40 miles wide, and furrowed by north-east and south-west ridges and depressions, parallel to the strike of the Cambrian and Silurian beds. Through this runs the Tennessee River, which, instead of running south to the Gulf of Mexico, turns to the north-west, some distance below Chattanooga, and cuts through the Cumberland table-land, a prolongation of the Appalachian Mountains, and flows into the Ohio River. The Cumberland table-land has an average height of 2000 feet above the sea, and 1350 feet above the Tennessee River at Chattanooga. It consists of a synclinal of Carboniferous rocks resting conformably upon the Devonian beds, and is bounded along the East Tennessee Valley by a curved escarpment; a similar though more indented escarpment forming its north-western margin, and separating it from the Silurian plain of Nashville. The table-land is about 40 miles wide, and is intersected by the Valley of the Sequachee River, running in a north-easterly direction along a subsidiary anticline from near Jasper for a distance of 60 miles. From the base of the Cambrian beds, the whole Lower and Upper Palæozoic formations succeed each other in apparently conformable sequence, except at the junction of the Upper and Lower Silurian series, where a probable discordance occurs. The prolonged period of subsidence and deposition at length gave way to elevation; acting with the greatest effect along the Alleghanies. Under these circumstances, denudation proceeded most rapidly along the tract bordering the Protaxis, whilst the synclines were protected from erosion to a greater degree; and as the elevatory movement was more rapid along the Unaka range, the flow of the streams was generally westward. At a later period the Cumberland plateau began to be formed by backward erosion of the strata in the direction of the dip; so that it owes its development to the erosion of the Tennessee and Clinch Rivers on the one hand, and to the Cumberland River on the other. Where the Tennessee River flows in a north-westerly direction through the Cumberland plateau, the divide between it and the Gulf of Mexico is only 280 feet above the river-bed, whilst the table-land is 1400–1500 feet above. The author infers, therefore, that when the river began to erode its channel the plateau was relatively lower than the tract to the south of the present course of the stream, but that by denudation the relations have been reversed, whilst the river has never left its originally selected course. The author compares the state of things with that which must have occurred in the case of the northerly rivers running from the centre of the Wealden axis; but mentions that Prof. Safford and Mr. J. Leslie account for the Cumberland plateau by faulting, though he thinks that the well-defined escarpment along the Valley of East Tennessee seems to show that this cause is insufficient. In conclusion, he believes that the denudation was accelerated during the pluvial or "Champlain" period, and calls attention to the "Columbia formation" of the east side of the Alleghanies, and to the deposit of red loam by which the surface of the country of the valleys of the Tennessee and Sequachee is overspread, and which is probably referable to a similar stage. After the reading of the paper there was a discussion, in which Mr. Topley, Prof. Hughes, Mr. Wills, Dr. Hyland, and the President took part. The President found difficulties here, as elsewhere, in realizing the form of the ground when the rivers began to flow, and in discovering whether there were subterranean movements which affected the denudation. He felt that the explanation of the topography might not be so simple as Prof. Hull made out, and would like to have more details as to the structure of the ground. The author, in reply, concurred with the remarks of the President as to the complex character of the subject.—On certain Ornithosaurian and Dinosaurian remains, by R. Lydekker.

Royal Meteorological Society, December 17, 1890.—H. F. Blanford, F.R.S., Vice-President, in the chair.—The following papers were read:—Note on a lightning stroke presenting some features of interest, by R. H. Scott, F.R.S. On January 5, a house near Ballyglass, Co. Mayo, was struck by lightning, and some amount of damage done. A peculiar occurrence happened to a basket of eggs lying on the floor of one of the rooms. The shells were shattered, so that they fell off when the eggs were put into boiling water, but the inner membrane was not broken. The eggs tasted quite sound. The owner's account is that he boiled a few eggs from the top of the basket, the rest were "made into a mummy," "the lower ones all flattened, but not broken."—Note on the effect of lightning on a dwelling-house, by A. Brewin. This is an account of the damage done to the author's house at Twickenham on September 23.—Wind systems and trade routes between the Cape of Good Hope and Australia, by Captain M. W. C. Hepworth. The author is of opinion that the best parallel on which commanders of vessels navigating the South Indian Ocean between the Cape of Good Hope and the Australian colonies should run down the longitude is between the 41st and 42nd parallels during the winter months, and between the 45th and 46th parallels during the summer months.—Report on the phenological observations for 1890, by E. Mawley. Taking the year ending August, the weather of the autumn, winter, and spring, and of the first summer month could scarcely have been more favourable for vegetation, while that of July and August proved altogether as unpropitious.—The climate of Hong Kong, by Dr. W. Doberck. This is a discussion of the meteorological results at the Hong Kong Observatory, and at the Victoria Peak, during the five years 1884–88.

CAMBRIDGE.

Philosophical Society, November 24, 1890.—Prof. G. H. Darwin, President, in the chair.—The following communications were made:—On the beats in the vibrations of a revolving cylinder or bell, and their bearing on the theory of thin elastic shells, by Mr. G. H. Bryan. It is well known that if a vibrating rod of circular section is rotated upon its axis the plane of vibration remains fixed in space instead of turning round with the rod—an experiment frequently used to illustrate the corresponding property of polarized light. If, on the other hand, a tuning fork is rotated, beats will be heard which indicate that the planes of vibration turn with the fork. In this paper it is shown that when a bell or other body symmetrical about an axis is vibrating, and at the same time revolving about that axis, an intermediate effect will in general be observed. The nodal meridians will rotate, but with a smaller angular velocity than the body. This is in the first place proved from general considerations for the case of a rotating ring or cylinder, which, as in the investigations of Hoppe and Lord Rayleigh, is supposed inextensible to the first order of small quantities. In the mathematical investigations which follow, the purely statical effects of centrifugal force are separated more easily by supposing the ring to be also acted on by an attraction to the centre proportional to the distance. Taking the type of vibration which has $2n$ nodes, the author finds that these nodes rotate about the axis with angular velocity

$$\frac{n^2 - 1}{n^2 + 1}\,\omega,$$

where ω is the angular velocity of the ring. The number of beats heard per revolution of the ring will therefore be

$$2n\,\frac{n^2 - 1}{n^2 + 1},$$

instead of $2n$, which would be the number if the nodes were to rotate with the ring. Putting $n = 2, 3$, &c., we find the numbers of beats per revolution corresponding to the successive tones to be 2·4, 4·8, 7·059, 9·231, 11·351, &c., approximately. The results of experiment were found to agree fairly closely with theory.—On liquid jets, by Mr. H. J. Sharpe.—Notes on the application of quaternions to the discussion of Laplace's equation, by Mr. J. Brill.—On a simple model to illustrate certain facts in astronomy, with a view to navigation, by Dr. A. Sheridan Lea.—Note on a paper in the Society's Proceedings, by Mr. W. Burnside.

PHILADELPHIA.

The Franklin Institute, November 18, 1890.—Chemical Section.—Alloys of sodium and lead, by Wm. H. Greene and Wm. H. Wahl. Recently, in the course of certain investigations, in which we had occasion to make use of alloys of lead and sodium, we found that the properties of such alloys did not correspond with what we had anticipated from previous publications on the subject, and we were led to an examination of the properties of lead-sodium alloys of definite composition. These alloys may easily be made by direct combination, and the products are then sensibly constant in composition, which is not the case when they are prepared by reducing lead oxide by carbon in presence of soda, or by heating litharge with sodium tartrate, as described by Vanquelin and Serullas. The required quantity of sodium was added to lead melted in a covered crucible, and the alloy was roughly analyzed by determining lead only. Our alloys contained from 3 to 31 per cent. sodium. They are all brittle and crystalline; all decompose water, that containing the least sodium producing a hardly perceptible evolution of gas, while that containing 31 per cent. reacts with violence. The brittleness and oxidability increase with the percentage of sodium. The richest alloy is greenish in colour, and instantly blackens on exposure to air. We made special examinations of the alloys corresponding in composition to Na_2Pb_2, Na_2Pb, and Na_4Pb: the first of these contained 10 per cent. sodium, the second 19·5 per cent., rather more than would be indicated by the formula, while the last contained 31·7 per cent. The densities were determined in aniline, and found to be considerably higher than would be the densities of mixtures of the same composition. Thus the 10 per cent. alloy has a density of 6·91, the 19·5 per cent. a density of 4·61, and the 31·7 per cent. alloy a density of 3·81. The densities of corresponding mixtures would be 5·6, 3·7, and 2·7 respectively. The theoretical and calculated percentages of Na in alloys of above assumed composition compare as follows:—

	Na_2Pb_2.	Na_2Pb.	Na_4Pb.
P.C. Na by theory	10	18·18	30·8
,, found	10	19·5	31·7

CONTENTS.

THURSDAY, JANUARY 8, 1891.

THE SOUTH KENSINGTON AND PADDINGTON SUBWAY RAILWAY.

WE print elsewhere a letter from General Webber, in which he begins by stating that the land at South Kensington which is under the control of the Exhibition Commissioners, was originally, to use the words of the late Prince Consort,

"At no distant date to form the inner court of a vast quadrangle of public buildings, rendered easily accessible by the broad roads which surround them, buildings where science and art may find space for development, with the air and light which are elsewhere well nigh banished from this overgrown Metropolis."

If General Webber had been merely a company-promoter he would never have supplied us with so apt a quotation, telling so dead as it does against his underground railway; but the fact is, his appreciation for science has unconsciously led him to give the scientific rather than the Stock Exchange view of the matter. By all means, we urge, let the destiny foreshadowed by the late Prince Consort be fulfilled, especially as regards the "buildings where science may find space for development."

Again, General Webber's sincerity compels him to be quite silent about the disastrous disturbance that his railway, if ever constructed along the route now proposed, would cause to the pursuit of scientific investigation in the various present laboratories in Exhibition Road. The only remedy he can suggest is that "laboratories and observatories for original research used for the instruction of a very few experts may have to find a home elsewhere." Now, even this remedy he would never have advanced had he realized that his "very few experts" are in actual fact some hundreds of students, all of whom are now daily using the very apparatus, and making the very experiments, that his railway would render impossible. And since many of these students are being trained to become teachers, the education now given to hundreds daily in Exhibition Road is indirectly the teaching of thousands throughout Great Britain.

But we will go farther and say that, even if the interests of large numbers of present and future students were not at stake, and even if General Webber's contention were correct, that the work of only a few experts would be stopped by his railway, that alone should compel the railway to seek another route. For the work of these few experts at South Kensington, some of whom are rapidly advancing pure science, and others of whom are as rapidly advancing applied science, will produce a far wider effect on the future of this country than the utilization or non-utilization of the existing subway by the South Kensington and Paddington Railway Syndicate.

Towards the end of his letter General Webber feels bound, however reluctantly, to act the true "company-promoter," and so he refers to "the steady annual decline in the records of the numbers of visitors to the permanent institutions," as an argument to show the necessity of a new mode of locomotion. Probably this reference to "the steady annual decline" is only a quotation from the prospectus of the "South Kensington and Paddington Subway Company," and so ought to be taken with that liberal seasoning of salt appropriate to prospectuses of new companies. For, as a matter of fact, "the steady annual decline in the records of the numbers of visitors" is disposed of at once on examining the records themselves, which give the following figures:—

Number of visitors to the South Kensington Museum, the Natural History Museum, the Indian Museum, and the Museum of Scientific Apparatus.

During	1886	1,206,741
,,	1887	1,146,590
,,	1888	1,270,027
,,	1889	1,235,854
,,	1890	1,187,142

from which we see that the numbers during the last two years together were actually larger than the numbers during the first two together.

General Webber says that by his proposed railway "easy and rapid communication will also be afforded to hundreds of thousands of persons living to the north of Hyde Park to visit and use all the great institutions collected at South Kensington." Would not the communication be just as easy and just as rapid if the railway went down Queen's Gate, and connected the Gloucester Road Station on the District Railway with Paddington? For the main entrances to the Albert Hall, the Natural History Museum, and the Imperial Institute, are just as near Queen's Gate as Exhibition Road. The South Kensington Museum is no doubt on the Exhibition Road side of the space, but to balance this the Exhibition of Machinery and Inventions is on the Queen's Gate side of the area in question.

The public will be equally well served along whichever of the two alternative sides of the Albert Hall the railway goes. But, while an untimely selection of the eastern, or Exhibition Road, route would mean a disastrous stoppage of the scientific work now being carried on, the trains might run along the western, or Queen's Gate, route without causing practically any magnetic or mechanical disturbance to the delicate instruments in use at the existing laboratories.

We shall probably be answered that, unless the present subway (the length of which, as a matter of fact, is but one-tenth of the whole length of the proposed railway) be utilized, the District Railway and General Webber's syndicate will not make quite so much money out of the scheme. Possibly not; but is the London home of scientific research to be destroyed merely to enable General Webber's syndicate to pay extra dividends?

"All attempts hitherto made to complete the work" (that is, the subway) "as far as the Albert Hall have failed," says General Webber. May his present scheme, the ill-omened child of many failures, say we, walk in the footsteps of its fathers.

ARE THE EFFECTS OF USE AND DISUSE INHERITED?

Are the Effects of Use and Disuse Inherited? An Examination of the View held by Spencer and Darwin. By William Platt Ball. (London: Macmillan and Co., 1890.)

THE question which constitutes the title of this essay still continues—and is likely for some time to continue—the most important question in the field of

Darwinian thought. On the one side we have the school of Weismann, which answers the question with an unequivocal negative. On the other side we have the writings of Darwin himself, which entertain the so-called Lamarckian factors as subsidiary to natural selection, or as lending considerable aid to natural selection in carrying out the work of adaptive evolution. Again, we have the writings of Herbert Spencer, which attribute a still higher proportional value to the Lamarckian factors; while, lastly, we have the self-styled neo-Lamarckians, who regard these factors as of even more importance than natural selection. Amid so great a conflict of opinions on a matter of such extreme importance, any survey of the actual evidences in favour of the Lamarckian factors cannot fail to be opportune, even though the value of such an attempt must depend upon the care and the judgment with which it is undertaken. Now, we are glad to say that the essay before us is, in all respects, as admirable as it is opportune. Scientific in spirit, and logical in execution, it deals with its subject in a manner at once concise and exhaustive. Restricting his ground for the most part to the domain of fact, Mr. Ball has made a full inventory of the cases, or classes of cases, which have hitherto been adduced in evidence of the transmission of acquired characters, and briefly weighs the value of the evidence in each. In the result he concludes that there is no real evidence for any of the cases; and as his work is throughout performed in a thoughtful and painstaking manner, we deem it the most instructive contribution which has hitherto appeared upon the subject of which it treats. Of course the writings of Galton and Weismann present the greater merit of having been the first publicly to challenge the doctrines of Lamarck; but this they did on grounds of general reasoning, and by viewing the evidences of those doctrines, as it were, *en masse*. The merit of Mr. Ball's work, on the other hand, consists in its detailed analysis of each of the facts and arguments which have ever been brought forward in support of what he conveniently calls "use-inheritance."[1] He thus restricts himself to the one question of fact, whether or not there is any good evidence of the transmission of acquired characters, without embarking upon any general theory of heredity. And, as already remarked, he has done this purely analytical work in an exceedingly able manner. So much, indeed, is this the case, that we can find but little to say in the way of criticism; and that little must take the form of pointing out the particular cases where it seems to us that his examination is not quite so thorough as it usually is.

He begins by taking *seriatim* "Spencer's examples and arguments," and the first of these is "diminution of the jaws in civilized races." Here he shows that "cessation of the process by which natural selection favoured strong thick bones during ages of brutal violence might bring about a change in this direction;" and he points to the simultaneous thinning of the skull, &c., as virtual proof that such is the true explanation. Nevertheless, in the next section, which treats of "diminished biting muscles of lap-dogs," he invokes the principle of artificial selection to explain the facts, thus: "The conscious or unconscious selection of lap-dogs with the least tendency to bite, would easily bring about a general enfeeblement of the whole biting apparatus—weakness of the parts concerned favouring harmlessness" (pp. 12, 13). But surely, if the cessation of selection is sufficient to account for the diminution of the biting apparatus "in civilized races of mankind," it is no less capable of explaining a similar diminution in the case of "lap-dogs." If artificial selection has taken any part in the matter at all, it must have done so in the direction of "favouring harmlessness" by acting on instincts or dispositions rather than on jaws and muscles (see NATURE, vol. xxxvi. p. 405).

In opposing Spencer's argument drawn from the facts of co-adaptation, Mr. Ball appears somewhat unduly to assume the character of a special pleader. The argument is, that the more the utility of any co-ordinated set of parts depends upon their co-ordination, the more difficult does it become to see how natural selection alone could have produced the mechanism. For if the mechanism be such that its utility depends on all its parts simultaneously co-operating, no utility can arise unless all the parts are developed simultaneously in the same individuals. Now, Spencer represents that the chances must be enormously against an accidental occurrence of many concomitant changes in any single individual, where such changes are thus without benefit to the individual save when they do occur in combination; while, of course, the inherited effects of use and of disuse of all the parts concerned would explain their simultaneous evolution. Mr. Darwin answered this argument by showing how natural selection might be held to operate in the production of these effects; but in doing so he continued to attribute a probably large share of the work to the Lamarckian (*i.e.* Spencerian) factors. Now, Mr. Ball, in quoting Darwin's opinion, ignores this latter point. For instance, after giving it as Darwin's view "that natural selection alone 'would have sufficed for the production of this remarkable quadruped'" (*i.e.* the giraffe), he omits the conclusion of Darwin's sentence, viz. "but the prolonged use of all the parts together with inheritance will have aided in an important manner in their co-ordination." Again, while referring to what Darwin has said touching another of Spencer's examples—the elk—Mr. Ball omits to notice the sentence: "Although natural selection would thus tend to give to the male elk its present structure, yet it is probable that the inherited effects of use, and of the mutual action of part on part, have been equally or more important."

In bringing together all the cases adduced by Darwin to support the theory of use-inheritance, Mr. Ball begins by observing that

"he [Darwin] appears to have acquired the belief in early life, without first questioning and rigorously testing it, as he would have done had it originated with himself. In later life it appeared to assist his theory of evolution in minor points, and in particular it appeared absolutely indispensable to him as the *only* explanation of the diminution of disused parts in cases where, as in domesticated animals, economy of growth seemed to be practically powerless. He failed to adequately notice the effect of panmixia, or the withdrawal of selection, in causing or allowing degeneracy and dwindling under disuse."

[1] This term is coined by him as equivalent to Darwin's "inherited effects of use and disuse," to Spencer's "inheritance of functionally produced modifications," to Weismann's "inheritance of somatogenetic characters," &c.

These remarks are very judicious, as likewise are those where, further on, he alludes to the important distinction between selection as merely withdrawn (panmixia) and as actively "reversed" (through economy of growth, &c.). For it is shown that, if Darwin had not thus failed adequately to notice the former principle without reference to the latter, he could not have continued to regard our domesticated animals as furnishing any conclusive proof of use-inheritance; or, indeed, any better evidence than is furnished by animals in a state of nature. Having satisfied himself that there can be no economy of growth in our highly-fed domesticated animals, seeing that parts may reappear in them which are obsolete in their parent or undomesticated types, he concluded that, where other parts presented diminution, the fact could not be attributed to a reversal of selection. Therefore he attributed it to the inherited effects of disuse as to the only imaginable alternative. But, as Mr. Ball—following Weismann and others—plainly shows, the mere cessation of selection, without any reversal of selection, is in all such cases bound to produce the effects observed; with the consequence that the former principle "invalidates Darwin's strongest evidence for use-inheritance."

Passing from such general remarks on Darwin's attitude of mind with respect to the question of use-inheritance, Mr. Ball deals separately and exhaustively with all the particular instances that Darwin has given. The criticism here is uniformly good, and as regards some of the cases—*e.g.* "wings and legs of ducks and fowls"——remarkably so. But as we have no space to consider these numerous instances in detail, it must be enough to say, in general terms, that Mr. Ball has certainly reduced their evidential value to very small dimensions. Even the results of Brown-Séquard's experiments on the apparent transmission of injuries are shown to be of a more doubtful character in relation to the question of use-inheritance than anybody else has hitherto indicated.

There are, however, two or three remarks which seem worth making on Mr. Ball's treatment of some of Darwin's examples. Thus, in considering the "larger hands of labourers' infants" as compared with those of infants belonging to the upper classes, he attributes the phenomena to "sexual selection in the gentry." And in many other cases, both in man and the lower animals, he shows how the apparent effects of use-inheritance may be due to this cause. Such, of course, is a very reasonable position for Mr. Ball to adopt; but what is to be said about all such cases by the school of Wallace, which rejects the theory of sexual selection as well as that of use-inheritance? These cases, of course, are cases where the theory of natural selection cannot be applied; and therefore it would seem that the school of Wallace must either confess them inexplicable, or else devise some additional theory for the purpose of explaining them.

This allusion to the views of Mr. Wallace leads to a consideration of an important argument recently published in his "Darwinism"—namely, that, even if use-inheritance be physiologically possible, it can never be allowed to act, inasmuch as natural selection will always effect the required alterations more rapidly than they could be effected by use-inheritance. The only answer to this argument appears to be, as Mr. Ball puts it, "that slight changes in each generation need not necessarily be matters of life and death to the individual, although their cumulative development by use-inheritance might eventually become of much service." This answer he disposes of by adding: "But selection would favour spontaneous variations of a similarly serviceable character." This, however, does not appear to meet the requirements of the case. For the whole point of the answer to Mr. Wallace's argument lies in the consideration that "slight changes in each generation need not necessarily be matters of life and death to the individual," *i.e.* that the amount of change due to use-inheritance may be so small *in each successive generation* as not to make any appreciable difference in the struggle for life. Hence this amount of change need not be in any degree "serviceable," although, by an accumulation of such changes in the same line of change, a high degree of serviceability may be attained without the necessary aid of selection. Of course, this answer to Mr. Wallace's argument can only go upon the supposition on which the argument itself is founded—namely, that use-inheritance is physiologically possible; and therefore both the argument and the answer are irrelevant to the question of such possibility as raised by Weismann.

Once more in the same section of this essay—namely, that which is concerned with Darwin's examples of use-inheritance—Mr. Ball repeatedly adduces the case of neuter insects as demonstrative evidence against use-inheritance. But he does not consider the possibility of the instincts of neuters being survivals from a time when all the female insects of a hive were both fertile and industrious. He quotes, indeed, an absurd passage from Büchner upon this subject, but does not allude to what Perrier has said. We are far from maintaining that Perrier has made out his case; but we think that the question raised by him ought to have been gone into by Mr. Ball. Moreover, in the event of there being a second edition of his essay, it is to be hoped that Mr. Ball will consider the ingenious suggestion with regard to these instincts which has just been published by Prof. Lloyd Morgan in his admirable treatise on "Animal Life and Intelligence," pp. 440–42.

The concluding part of the treatise is devoted to "Miscellaneous Considerations." These all appear to us both apposite and cogent, except the sections which argue that use-inheritance, even if it were physiologically possible, would prove of more harm than good in the matter of adaptive evolution. In the first place, there was no necessity for Mr. Ball to propound such a question—his aim elsewhere being to show that, as a matter of fact, there is no evidence of use-inheritance having ever been in operation. In the next place, this foreign and superfluous argument is not well sustained; for although Mr. Ball shows that in many instances use-inheritance would be an "evil," he not only disregards the vastly greater number of cases in which it would helpfully co-operate with natural selection, but he also disregards the important consideration that in all cases the "minor factor" would require to be under control of the "major factor"—with the result that, where harmful, its effects would not be allowed to develop.

Although we have thus devoted considerable space to a review of this little book, we regret our inability to devote more. For, having restricted ourselves to points where criticism seems possible, we must have failed to give a sufficient idea of all the rest of the essay. In conclusion, then, we must add that Mr. Ball's analysis as a whole appears to us to stagger the theory of use-inheritance more seriously than ever it has been staggered before; and, therefore, that no one who henceforth writes upon the subject can afford to disregard his treatment of the question, "Are the Effects of Use and Disuse Inherited?" George J. Romanes.

TECHNICAL EDUCATION.

Manual Training in Education. By C. M. Woodward, A.B., Ph.D. (W.U.), &c. With Illustrations. (London: Walter Scott, 1890.)

THIS is in some respects a valuable work, and therefore it is the more to be regretted that its title is in a double sense misleading. A very little reflection would have taught the author that "manual," as from *manus*, the hand, means anything which hands are capable of effecting. He, however, defines "manual training" as limited to teaching and learning the use of tools and working materials; these, according to his system, being limited in turn to wood and metal work, such as turning, carpentry, and smithing. The immense range of work of which children are capable is not included, therefore, in "Manual Training." Again, we find in the book that the education in question not only does not include that of girls, but actually takes no note of young children of either sex. "Starting with boys in their teens," Prof. Woodward shows, what has always been well known, that such boys can be taught the rudiments of certain "trades." But as the very great majority of children leave school early in their teens to go into active life, what parents or the public chiefly wish to know is, what manual training can be imparted to all children while they are yet at school? Extensive experiment has perfectly shown that they can be taught to draw, model, and execute much useful art work even from six years of age, and what is of more importance is that, as one hour of sleep before midnight is worth two after it, so those who learn to draw in early childhood acquire a certain dexterity and skill such as is rarely, if ever, attained after thirteen years of age. "The proper mental maturity," says Prof. Woodward, "rarely comes before the fourteenth year. I think of the class as about fifteen years old." "The minimum rate of admission" (to my school) "is fourteen years"—meaning, we suppose, that no younger pupils are received. If this means anything, it is that, according to the author, manual training in education should not begin till "the proper mental maturity" is attained. But what we expect from education is that pupils shall be trained *before* their minds are matured.

There are many persons who will buy this work under the impression that it will teach all the details of manual training. But, in fact, of its 310 pages only 77 are devoted to practical instruction in drawing, wood and iron work. These are truly excellent of their kind, so much so that we cheerfully wish *si sic omnes*—"would that all were like it"—since in that case we should have had a work of practical use, although there is at present no lack of admirable if not better hand-books for such training in England. In the remaining part of the book Prof. Woodward advances theories which no man of culture and intelligence can admit, and which imperatively call for refutation, since at present the British public in its bewilderment as to "technical education" is being extensively deluded by them.

It has been said by some journalist that the aim of the Socialists seems to be to make of all society a well-organized poor-house. It is not in the least an exaggeration to say that Prof. Woodward's idea of education is that every male in a community shall be, first of all, a mechanic. He admits, it is true, a moderate amount of culture in literature and other branches, but exacts that *three hours a day* shall be given to drawing and manual labour, while with boys above fourteen it may be more. That is to say, three hours in school, with two hours of home study, are to be given to mathematics and book-keeping, science (*i.e.* geography, zoology, botany, chemistry, physics, physiology) and literature (which is to include "some choice specimens of modern prose and poetry"), and *one* foreign language—French, German, or Latin. But it is very evident that Prof. Woodward considers that in all cases, with every pupil, the manual labour should be the most thoroughly taught, and that carpentry and metal work are of paramount importance. The main force or tendency of all education should be to form a mechanic, and give to every youthful mind the habit of regarding all things from a mechanic's point of view.

Now, while this is a commendable education for a blacksmith, and while we may admit that it amuses and pleases youth, it is evident "on the face of it" that the literary course prescribed is utterly inadequate to *properly* prepare pupils for any career above that of the workshop. And this tone pervades the whole book: "there's nothing like leather" appears on its every page. The author quite forgets, what is also left out of sight by most of our own reformers in education, that, absolutely necessary as it may be to educate the majority to become mechanics, the world requires a very respectable number of professional, literary, and really scientific men, who could not be properly trained for such pursuits on one language, even with a knowledge of "some choice specimens of *modern* prose and poetry."

It is true that the author admits that, when "a lack of mechanical interest or power" manifests itself, the lad should unquestionably be sent to his grammar and dictionary rather than to the laboratory and drafting-room." That is to say, when the bit of wood is fit for nothing else we may make a god of it. And a master mechanic is to decide as to who shall thus take the back seats in education, and occupy the inferior positions of men of science and literature!

There is a class of boys, according to Prof. Woodward, "who are so constituted that their controlling interests are not in the study of words, the forms of speech, or the boundless mass of information which is given in books." These appear to be his favourites. "The claims of this class of boys," he asserts, "have been set forth by no one so eloquently as by General Francis A. Walker." It may interest the reader to see what is regarded as surpassing eloquence by one who prescribes the limits of all literary education.

"It not infrequently happens that the boy who is regarded as dull because he cannot master an artificial system of grammatical analysis, who isn't worth a cent for giving a list of the kings of England, who doesn't know and doesn't care what are the principal productions of Borneo—has a better pair of eyes, a better pair of hands, a better judgment, and even by the standards of the merchant, the manufacturer, and the railroad president, a better head than his master."

The reader has possibly heard such brilliant eloquence at a certain class of popular meetings, where the assertion that the ignorant and book-hating man is the cleverest in the community is always received with cheers. Prof. Woodward himself asks if there "may not be something mischievous in the power of attention to certain book-learning, as shown by the tendency of bookish people to dislike manual labour, and sometimes to become bad citizens?" It is evident enough that "bookish people" do not stand high in his graces. He assures us that his manual education is carried on in the interest of rational intellectual training and culture, but we confess that we fail to see it. These extracts indicate exactly what his standard of "culture" must be. Indeed, he declares that his system, far from being too narrow, is rather too broad.

We cordially believe that Prof. Woodward is an accomplished, skilful, very earnest and successful teacher of wood and metal work to boys over fourteen or fifteen years of age, but we have rarely met with a writer who needed more the caution not to go beyond his last. His work is to all intents and purposes inspired with the belief that all schools should be like his own, and all education for all classes be based on the very limited mechanical training with which he is familiar. That it is admirable to a certain degree, but most inadequate to all the demands of a really good education, is apparent on every page. As he handles all his adversaries without gloves, sparing no one who does not believe his method of education to be perfection, we have the less scruple in setting forth the truth regarding it in plain words. Singular as it may seem, not only to him, but to a great number of reformers, the education of the future will require a much higher stimulant or a far better basis than mere mechanical drawing, hammering, and filing.

OUR BOOK SHELF.

Monographie der baltischen Bernsteinbäume: Vergleichende Untersuchungen über die Vegetationsorgane und Blüthen, sowie über das Harz und die Krankheiten der baltischen Bernsteinbäume. Von H. Conwentz. Pp. 151, mit achtzehn lithographirten Tafeln. (Danzig. London: Williams and Norgate, 1890.)

DR. CONWENTZ was long associated with Goeppert and Menge in the investigation of the "Amber Flora," and indeed wrote the whole, or nearly the whole, of the second volume of the "Flora des Bernsteins," comprising the angiospermous fossils found in Baltic amber. Engaged upon a third volume of this work, devoted to cryptogamous or spore-bearing plants, Dr. Conwentz became impressed with the necessity of first working out the relationships of the trees which yielded the resin now found in a fossil state and known as amber, and those who know the admirably executed plates and exhaustive text of the two volumes issued of "Die Flora des Bernsteins" will not be disappointed with this companion volume.

We cannot attempt a critical review of this work, and must therefore be content with giving the result of Dr Conwentz's investigations, as set forth by himself. During the Tertiary period the division or distribution of land and water, especially in Europe, was very different from what it is at the present time; and in Eocene times, the beginning of this period, the Scandinavian continent extended southward nearly to the Samland district of northern West Prussia and Mecklenburg, and supported a vegetation whose principal types now characterize the flora of the southern parts of the temperate zone and the northern subtropical zone. Evergreen oaks and beeches flourished, associated with palms, laurels, magnolias, and camellias; also the amber trees and various kinds of cypress.

Chief among these amber trees were four species of *Pinus*, not one of which was very closely related to *Pinus sylvestris*, the characteristic fir or pine-tree of the region of the present period. One of the species, with leaves or needles in pairs, recalls some of the North American species belonging to the section *Parrya;* a second resembles the Japanese *Pinus Thunbergii;* and a third, having the leaves in fascicles of five, is near *P. Cembra* and the Japanese *P. parviflora.* In addition there was a kind of spruce more nearly allied to *Picea ajanensis*, of the extreme east of Asia, than to the silver spruce of Germany.

It is probable, Dr. Conwentz believes, that all these different trees and shrubs did not form a mixed forest, but were peculiar to separate regions, and then the amber trees formed dense forests interspersed here and there only with other trees. Dr. Conwentz pictures the conditions under which he imagines these amber trees existed and discharged the resin now so universally employed. The trees he assumes were exposed to the ravages of almost numberless enemies, animal and vegetable, insomuch that there was scarcely a sound tree in the forests. The trees thus enfeebled would be swept down or mutilated by violent storms, causing an abnormal exudation of resin. It seems, however, hardly necessary to insist on the general unhealthiness of the trees to account for the large deposits of resin. Clouded amber is said to be due to the presence of cell-sap in the resin. The majority of the plates illustrate the destruction of the tissues by various fungus parasites. W. B. H.

The Birth and Growth of Worlds. By A. H. Green, M.A., F.R.S. (London: Society for Promoting Christian Knowledge, 1890.)

THIS little work is the extension of a lecture delivered by Prof. Green. It contains an account of various cosmical theories from 1684, when Thomas Burnet, D.D., a learned divine, expounded his "Sacred Theory of the Earth," to recent times. The researches of Prof. Lockyer on the constitution of the heavenly bodies are well described; as are also the hypotheses of Kant and Laplace. A list is given of the chief works bearing on the subject of the lecture. This, in conjunction with the descriptive text, and a few well-chosen illustrations, renders the book extremely useful as a popular short exponent of the many attempts that have been made to fathom the origin of celestial species.

Chambers's Encyclopædia. New Edition. Vol. VI. (London and Edinburgh: W. and R. Chambers, Ltd., 1890.)

THE present volume of the new edition of Chambers's well-known "Encyclopædia" takes in words ranging from "Humber" to "Malta." In every respect it is up to the level of the preceding volumes; and, as usual, scientific subjects have been entrusted to thoroughly competent writers. Under "Hydrophobia" M. Pasteur sketches his discoveries and practices in regard to rabies, while Mr. J. Arthur Thomson contributes "a brief unargumentative review of current adverse criticism." There is an excellent article on insanity by Dr. T. S. Clouston. Prof. James Geikie writes on igneous rocks and other subjects; Prof. C. G. Knott on hydrodynamics and terrestrial magnetism; Dr. J. Anderson on lake dwellings; Dr. Alfred Daniel on light, lenses, and magnetism; Mr. R. T. Omond on lightning; and Mr. F. E. Beddard on the lion and the leopard. Iceland is described by M. Hjaltalín; India by Sir Richard Temple; the Indian Ocean by Dr. John Murray; the geography of Italy by Mr. W. D. Walker; and Madagascar by the Rev. J. Sibree.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Shaking the Foundations of Science.

MY attention has been drawn to the article in NATURE under the above title, and, as it presents to your readers the proposed South Kensington and Paddington Subway in an aspect which the writer erroneously describes as "the hosts of Mammon threatening the domains of science," I feel sanguine that a scientific journal such as yours will be even more than ordinarily desirous to have the correct view set before them.

The writer appears to ignore the fact that the rectangular area bounded by Kensington, Cromwell, Exhibition, and Prince Albert (now Queen's Gate) Roads forms part of the estate purchased out of the surplus funds of the Great Exhibition of 1851, and vested in a body of Commissioners by Royal Charter; and that this land was originally destined, to use the words of the late Prince Consort, "At no distant day to form the inner court of a vast quadrangle of public buildings, rendered easily accessible by the broad roads which surround them, buildings where science and art may find space for development, with the air and light which are elsewhere well nigh banished from this overgrown Metropolis."

The site of the Exhibition of 1862, and of the buildings of the South Kensington and Science and Art Departments, originally formed part of that estate.

When the Royal Albert Hall was first projected, a pneumatic railway from it to the South Kensington Station *viâ* Exhibition Road formed part of the original scheme, which was promoted by the Commissioners who own the estate, and the paramount necessity of such a means of communication has never been lost sight of.

When the existing subway was constructed in 1885, its continuance as far as the Albert Hall was a recognized part of the project, and the route alongside of the Eastern Arcades was then decided upon by the Commissioners. When the District Railway Company obtained their Act of Parliament for the subway, its use with traction was sanctioned.

The proposal now before Parliament is for absolutely no more and no less, so far as the estate of the Commissioners of 1851 is concerned, than the completion of that subway, with nearly its present form and dimensions, and with almost the same powers to use it in the same way.

All attempts hitherto made to complete the work as far as the Albert Hall have failed, and the existing incomplete portion of the subway is practically closed, and is a dead loss financially.

At last a practical solution of the difficulty has been found, with the additional advantage that, besides the means of covered access being afforded from South Kensington Station through the length of the estate, easy and rapid communication will also be afforded to hundreds of thousands of persons living to the north of Hyde Park to visit and use all the great institutions collected at South Kensington, to which covered access will thus further be secured from all parts of the metropolis.

In his eagerness to prove that the present means of access are all that can be desired, your contributor refers to the congregations of visitors attracted by former Exhibitions. The steady annual decline in the records of the numbers of visitors to the permanent institutions is not the only evidence which entirely refutes such a misleading line of argument.

I do not dispute for one moment that Urania must have her quiet retreats secluded from the movements and throng of men and vehicles, and it is hardly surprising that, as your contributor states, the repose she loves cannot even now be found at South Kensington.

But it is pure affectation to contend that the interests of the highest scientific education for the many will suffer, because laboratories and observatories for original research used for the instruction of a very few experts may have to find a home elsewhere.

If the vibration caused by omnibuses by day and market carts by night, passing in the Kensington and Cromwell Roads at each end of Exhibition Road, to say nothing of "small and earlies," are found already to affect the ultra-sensitive nerves of Urania, the question may be asked why the Professors continue to countenance the expenditure of the "vast sums" mentioned by your contributor, and also, if it is right that any more public money should be allowed to be spent in a way which experience has already shown to be injudicious.

It appears, therefore, evident that the degree to which the traffic in the proposed subway might augment this inconvenience does not affect the true merits of the case as set up by your contributor. C. E. WEBBER.

17 Egerton Gardens.

The Darkness of London Air.

THE interesting article on the above subject which appeared in your issue of December 18 (p. 152) is one of those periodical reminders that Englishmen—as if not content with the innumerable climatic ills to which they are unhappily heirs—are yearly endeavouring their "level best" to make city life more and more polluted and noxious. It is apparently in vain that they are constantly shown how injurious to human comfort in every way, how fatal to plant life, and how destructive to architecture, is this accumulation of unburnt fuel in the air; neither, strange to say, are they more heedful of the enormous annual waste, sheer waste, of fuel: to all arguments and expostulations they oppose stolid apathy. Seeing how hopeless it is to induce any active interest in this question among the inert mass of citizens, your contributor very sensibly suggests an appeal to the County Council to take up the matter. My object in writing is to offer a further suggestion on the *modus operandi*. Why not invite the Councils of all our learned and scientific Societies and institutions to combine in a memorial to either the County Council or Parliament direct, asking for legislation on this smoke question, and for simple machinery to enforce such legislation? I cannot but think that such a memorial, signed by, *e.g.*, the Royal Society, the Chemical, Linnean, Astronomical, and the various other Societies, by the College of Surgeons, the Royal Academy, and in fact by the representatives of all such corporations would carry very great weight. F. H. P. C.

A Remarkable Flight of Birds.

I HAVE not noticed any reference to the extraordinary flight of birds that was observed in many parts of Devon on the morning of December 21, after the first heavy fall of snow took place at the beginning of the present severe weather. At eight o'clock on Sunday morning I was astonished at a continuous stream of skylarks flying overhead in a westerly direction. The flight continued for more than an hour after that in the most astonishing numbers. Over 500 were counted in three minutes, and the cloud of birds seemed endless in every direction. An old farmer here said that he had seen a similar thing about ten years ago. The birds then were found on the estuaries, and by the sea-coast of Cornwall, where they died by thousands. Several letters have appeared in the local papers announcing a similar migration on the same morning, so that there must have been millions of birds on the wing. One correspondent mentions other birds, thrushes and blackbirds, &c., as well, but here I saw only skylarks. I have seen no record of their destination. It would be interesting to know if any of your readers could tell us where the birds went. They were all flying towards Cornwall. I observed also large detached flocks of plover, flying towards Dartmoor, on the edge of which I live, in a southerly direction. The appearance of these birds all hasting away in perfect silence was almost weird in the dead stillness, all the ground and every twig and bush being covered with deep snow, and not a breath of wind stirring.

The event has certainly justified their instincts, for until to-day, January 1, it has been almost impossible for the birds to obtain any food, except from the berries, which this year are exceptionally plentiful.

Large flocks of fieldfares have taken possession of my garden, where there are a great many hollies, and at any noise they rush out of the bushes like a swarm of flies. It is curious to watch them from the windows in the morning, some ten or a dozen sitting in the snow under the bushes, mere dejected heaps of feathers, occasionally pecking at the berries that their busy comrades have knocked off. The thrushes are in the wildest excitement. They sit above the hollies, quivering and chattering, and occasionally darting upon a luckless fieldfare, whose unwonted presence they resent most strongly. I do not know how these birds discover the berries. It cannot be by their colour, for there are two large hollies within ten yards of each other; one of them was for days full of birds constantly flying past the other, which was almost a mass of brilliant red berries. One tree was almost stripped bare, and the birds all went to an adjoining field for three days. Then one morning I found them in the remaining bush, which they speedily stripped as bare as the rest.

Throwleigh Rectory, Devon, January 1.

On the Flight of Oceanic Birds.

THE oceanic soaring birds undoubtedly take advantage of the air-currents as sailing-vessels do, trimming their wings so as to be acted on by the wind to the best advantage. I have frequently observed their flight in high southern latitudes, and have seen the sooty albatross sail round, and up and down, for ten minutes and more with never a flap of the wings; but with a pair of binoculars the tail, head, and portions of the wings could be seen to move slightly with each change of direction or elevation.

There are two well-marked ways of flying, as follows: (*a*) when the bird is flying with the wind blowing sideways on to it, as represented in Fig. 1, where it will be seen the whole of the

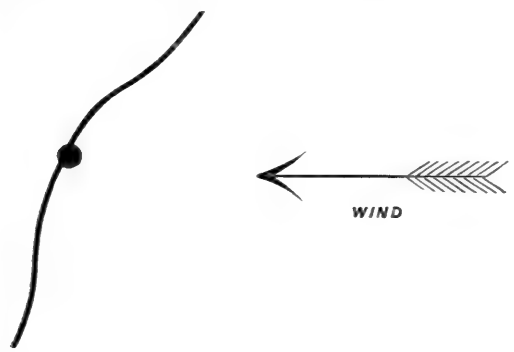

FIG. 1.—"On a wind."

under surface is exposed to the wind; and (*b*) when the bird is flying either directly towards or from the direction of the wind, as in Fig. 2, in this position a slight movement of the tail sending the bird up or down, and of the wings (not a flap) altering the direction.

Roughly speaking, the area of wing surface exposed to the wind is about 3 square feet, and the weight of the bird 7 pounds (sooty albatross). In all these true oceanic birds the wings are long and narrow, and the birds appear to have great power over the movements of the different joints.

FIG. 2.—Before or against the wind.

In calm weather the birds constantly settle on the water, and when flying flap their wings a good deal. As the wind makes and increases, the flaps become less in number, until the birds sweep round and under the stern of the ship in immense circles at the rate of 20 to 30 miles per hour, in most cases as represented in Fig. 3, at the part marked (*a*) close to the sea surface, and at (*b*) high in the air.

It is a common thing in high winds to see them apparently motionless for some time over the mast-heads, the ship at the same time going through the water at a speed of 10 or 11 knots per hour.

I would not pretend in any way to explain their marvellous flight, but one thing should be remembered, that the velocity of the air certainly increases from the surface of the sea to the altitude to which they attain, viz. about 200 feet; and that

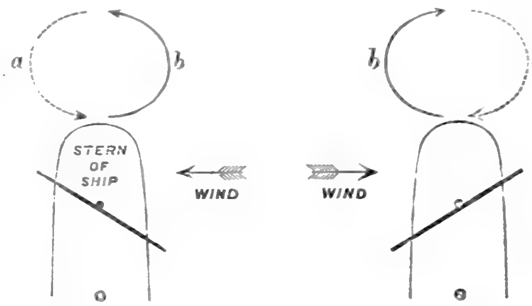

FIG. 3.

when the wind is strong the sea is thrown into considerable waves, which may affect the horizontal movement of the wind in immediate contact with them. There certainly seems to be some connection between the way the wings are spread to the wind's direction, the sliding up and down in their sweeping circle (Fig. 3), and their method of flight.

DAVID WILSON-BARKER.

The Locomotion of Arthropods.

I HAVE been making some observations on the locomotion of various insects, and find that in the case of those which move quickly the best method for observation is instantaneous photography. Instantaneous photographs of moving flies show that they move the front and hind leg of one side almost simultaneously with the middle leg of the other, while they stand on the other three. When the tripod which is moving has come to the ground, the other tripod is raised, and so on. The photographs show, however, that while no leg of one tripod ever moves simultaneously with any leg of the other, yet there is a succession in the movements of the legs of each tripod. The hind leg on one side is first moved, then the middle on the other, and when the hind leg has been moved forward and almost reached the ground, the front leg of that side is raised. The middle leg and the front leg of the opposite sides come to the ground almost simultaneously. It is usually just when the hind leg is reaching the ground, and the front leg is being raised, that the tripod on which the fly is resting thrusts the body forward. After the movement of each tripod there appears to be a short pause, during which all six legs are on the ground together.

I have observed this "tripodic" walk in earwigs, water scorpions, aphides, and some beetles. In the case of some slowly moving beetles and aphides which can be observed without photographic means, quite irregular movements have been observed. By cooling aphides, they can be made to move very slowly. In this condition one was observed to move its legs in slow succession in the following order: (1) right hind, (2) right middle, (3) right front, (4) left hind, (5) left middle, (6) left front. This walk was continued for some time, occasionally interrupted by the following order, or some other quite irregular walk: (1) right hind, (2) right middle, (3) left hind, (4) left middle, (5) left front, (6) right front.

In caterpillars the legs forming a pair seem to move simultaneously; the motion begins at the posterior end of the body, and proceeds regularly forward till the most anterior pair of legs are moved.

The above few observations, which were made in the Physical Laboratory of Trinity College last spring, formed the subject of a recent communication to the Dublin University Experimental Association. I hope to be able to extend this application of photography to the other groups of Arthropoda.

H. H. DIXON.

Physical Laboratory, Trinity College, Dublin.

P.S.—In taking the photographs a small camera with magnifying lens and fast shutter were used, and the analyses of the motions arrived at by the comparison of a large number of "snap" pictures. The insect was in each case placed on a white ground within a shallow box covered with glass and illuminated by oblique sunlight. In this way the disposition of the shadows became of great service in determining the positions of the legs.

Attractive Characters in Fungi.

No doubt the characters of the fungi mentioned by Mr. C. R. Straton on p. 9 are attractive, but it does not follow that they are useful. Mr. Straton's letter contains many incorrect statements: the importance of colours and odours to flowering plants cannot be correctly said to be "perfectly understood"; fungi are not "insusceptible of fertilization"; the common mushroom has no "parasitic period," and the first stage of its existence is not "passed in the body of an animal host."

The common mushroom never grows on the droppings of the horse, or upon the droppings of any other animal, and it cannot even be made to grow artificially upon fresh dung. An admixture of earth with decayed dung is required before mushrooms will grow. The mushroom is not a dung-borne fungus at all. It grows in pastures in common with a vast number of other pasture-fungi, and if we allow that the spores of the mushroom must needs first germinate in an animal stomach, it would be but reasonable to assume that the spores of other pasture-fungi would have a similar habit. The mycelium so commonly seen on horse dung is not the mycelium of the mushroom; it belongs to various dung-borne *Coprini*, and it is certainly not necessary for the spores of these *Coprini* to pass through a horse's intestinal canal, as they will readily germinate, not only on and in dung and its juices, but on wet blotting-paper, and on almost any other non-corrosive damp and warm material.

Mr. Straton seems to have a remarkable idea of the nature of a "parasite"; because an animal swallows spores, therefore the spores on being swallowed become "parasites." He might as reasonably describe the seeds eaten by graminivorous animals as "parasites," or the seeds of the strawberry and raspberry, when eaten with the pulp by man, as "parasites" in the human system.

As Dr. Cooke, in his interesting letter on p. 57, has not mentioned one special character of certain fungi which has greatly interested me, I may venture to advert to it here. I refer to *gluten*. Many fungi, especially Agarics, are highly glutinous, and if this gluten is not "attractive," it is, I think, useful.

Agaricus radicatus is one of our commonest stump-fungi; it has, when young, a *perfectly dry* pileus. As the fungus reaches maturity, the pileus becomes *glutinous*. The change reminds one of the change in the condition of the stigma in flowering plants. If sections are made through the pileus of *A. radicatus* in different stages of growth, it will be found that as maturity is gradually reached the centre of the pileus softens and swells, and through the now soft mass an enormous number of cystidia protrude themselves. The cystidia exactly resemble the cystidia of the gills. The cystidia open at the apex, and gluten exudes through the open mouths on to the cap of the fungus. If the sticky material from a mature example is microscopically examined, it will be found more or less full of germinating spores, which have been wafted on to the sticky pileus by the wind. The gluten possibly aids germination, if it does not—as I believe it does—cause fertilization.

Agaricus mucidus has a highly glutinous pileus, and it grows in such a fasciculose and closely imbricated manner on beech trunks, that all the spores from the upper examples fall of necessity on to the thick gluten of the examples immediately underneath. If the gluten is microscopically examined, it will be found full of the germinating spores of *A. mucidus*. The uses of the gluten here seem obvious. The simple spores of an Agaric might have but a poor chance of effectually germinating and growing upon a beech trunk, but if the spores had previously germinated and formed a mycelium in a highly glutinous material, they would have a fairly good chance. The sticky pileus would at length be blown from the beech trunk by the wind, and its mucidous character would cause it to stick to the first trunk or branch it might be blown against, and so the gluten and its living mycelium would become attached to a fresh host. *A. mucidus* is peculiar to beech woods.

I could extend these notes to other gluten-bearing fungi, as *A. adiposus*, &c., as well as to Agarics with glutinous stems; but the two examples above given may serve as a hint to other observers.

How have truffles acquired their subterranean habit? They are always eagerly eaten by pigs, squirrels, rats, and other animals when they grow near the surface, and the deeper placed examples alone survive. Would the constant destruction of tubers near the surface at length bring about a subterranean habit? WORTHINGTON G. SMITH.

Dunstable.

UNDOUBTEDLY there are numerous glutinous fungi, and the coating of gluten has a useful purpose. Whether Mr. Worthington Smith has quite apprehended the nature of that purpose may be an open question. The majority of the species in the genus *Hygrophorus* are glutinous, and this genus, as a whole, is about the latest in its time of appearance in the autumn. It is very suggestive to observe them apparently unharmed by frost, whilst the Agarics have collapsed, and are in rapid decay. That the glutinous coating is in this instance a protection from frost can scarcely be denied. Dr. Quelet, the French mycologist, has stated that in the Vosges some species of *Hygrophorus* do not appear until the early frosts have commenced, and he has borne testimony to the fact that they flourish in frosty weather without apparent injury. Both the species of Agaric to which Mr. Smith alludes, *Agaricus mucidus* and *Agaricus radicatus*, may be found late in the season, apparently indifferent to the frost, which affords a suspicion that the glutinous coating is a protection from frost. *Agaricus carbonarius* is viscid, but much more so as cold increases, and for two consecutive years we have watched it growing uninjured far into January, when no other Agaric could be seen. We do not contend that the "useful purpose" is in *all* cases a protection from frost, because in some early species we imagine it serves primarily as a protection against evaporation. Presuming that Agarics may contain more than 80 per cent. of water, such a protection would be of service to species growing in exposed situations. If Mr. Smith's suggestion as to *Agaricus mucidus* is accepted, it can only apply to that species, and *Agaricus adiposus*, and one or two others, as the majority of tufted species growing on trunks are not glutinous. Another explanation must be found for the whole *Myxacium* section of *Cortinarius*, for *Gomphidius*, for many of the *Boleti*, and for such Agarics as *Agaricus æruginosus*, *Agaricus semiglobatus*, *Agaricus lentus*, *Agaricus glutinosus*, *Agaricus roridus*, and many others. The idea that gluten "causes fertilization" is a novel one, and may be held as a private opinion, but cannot be accepted generally without evidence much stronger than individual belief; hence, although put forward by so experienced a mycologist as Mr. Worthington Smith, it must *not* be accepted as an admitted fact, but only as an individual opinion. M. C. COOKE.

THE RESEARCHES OF DR. R. KŒNIG ON THE PHYSICAL BASIS OF MUSICAL SOUNDS.[1]

II.

SO far we have been dealing with primary beats and beat-tones; but there are also secondary beats and secondary beat-tones, which are produced by the interference of primary beat-tones. An example of a secondary beat is afforded by the following experiment. Recurring to the preceding table of experiments, it may be observed that when the two shrill notes, ut_6, sol_6, giving the interval of the fifth, are sounded together, the inferior and superior beat-tones are both present, and of the same pitch. If, now, one of the two forks is lightly loaded with pellets of wax to put it out of adjustment, we shall get beats, not between the primary tones, but between the beat-tones. Suppose we add enough wax to reduce the vibration of sol_6 from 3072 to 3070. Then the positive remainder is 1022, and the negative remainder is 1026; the former being ut_5 flattened two vibrations, the latter the same note sharpened to an equal amount. As a result there will be heard four

[1] By Prof. Silvanus P. Thompson. (Communicated by the author, having been read to the Physical Society of London, May 16, 1890.) Continued from p. 203.

beats per second—secondary beats. Similarly, the intervals 2 : 5, 2 : 7, if slightly mistuned, will, like the fifth, yield secondary beats. Or, to put it in another way, there may be secondary beats from the (mistuned) beat-tones that are related (as in our experiment) in the ratio 1 : 1, or in the ratios 3 : 4, 3 : 5, &c., and even by those of 1 : 2, 4 : 5, 4 : 7, and so forth.

I have given you an example of secondary beats: now for an example of a secondary beat-tone. This is afforded by one of the previous experiments, in which were sounded ut_6 and the 11th harmonic of ut_3. In this experiment, as in that which followed with the 13th harmonic, two (primary) beat-tones were produced, of 768 and 1280 vibrations respectively. These are related to one another by the interval 3 : 5. If we treat these as tones that can themselves interfere, they will give us for their positive remainder the number 256, which is the frequency of ut_4. As a matter of fact, if you listen carefully, you may, now that your attention has been drawn to it, hear that note, in addition to the two primary tones and the two beat-tones to which you listened previously.

In von Helmholtz's "Tonempfindungen," he expresses the opinion that the distinctness with which beats are heard depends upon the narrowness of the interval between the primary tones, saying that they must be nearer together than a minor third. But, as we have seen, using bass sounds of a sufficient degree of intensity and purity, as is the case with those of the massive forks, beats can be heard with every interval from the mistuned unison up to the mistuned octave. Even the interval of the fifth, ut_1 to sol_1, gave strongly-marked beats of 32 per second. When this number is attained or exceeded, the ear usually begins to receive also the effect of a very low continuous tone, the beats and the beat-tone being simultaneously perceptible up to about 60 or 70 beats, or as a roughness up to 128 per second. If, using forks of higher pitches but of narrower interval, one produces the same number of beats, the beat-tone is usually more distinct. Doubtless this arises from the greater true intensity of the sounds of higher pitch. With the object of pursuing this matter still more closely, Dr. Kœnig constructed a series of 12 forks of extremely high pitch, all within the range of half a tone, the lowest giving si_6 and the highest ut_7. The frequencies, and the beats and beat-tones given by seven of them, are recorded in Table III.

TABLE III.

Frequencies of Forks.	Ratio.	Beats (Calcd.)	Resulting Sound.
ut_7 4096 and si_6 3840 ...	16 : 15	256	ut_3
,, 3968 ...	32 : 31	128	ut_2
,, 4032 ...	64 : 63	64	ut_1
,, 4048 ...	256 : 253	48	sol_{-1}
,, 4056 ...	512 : 507	40	mi_{-1}
,, 4064 ...	128 : 127	32	ut_{-1}
,, 4070 ...	158 : 157	26	—

The first of these intervals is a diatonic semitone; the second of them is a quarter-tone; the third is an eighth of a tone; nevertheless, a sensitive ear will readily detect a difference of pitch between the two separate sounds. The last of the intervals is about half a comma.

These forks are excited by striking them with a steel hammer. Some of the resulting beat-tones will be heard all over the theatre; but, in the case of the very low tones of 40 and 32 vibrations, only those who are close at hand will hear them. The case in which there are 26 beats is curious. Most hearers are doubtful whether they perceive a tone or not. There is a curious *fluttering* effect, as though a tone were there, but not continuously.

We have seen, then, that the beat-tones correspond in pitch to the number of the beats; that they can themselves interfere, and give secondary beats; and that the same number of beats will always give the same beat-tone irrespectively of the interval between the two primary tones. What better proofs could one desire to support the view that the beat-tones are caused, as Dr. Young supposed, by the same cause as the beats, and not, as von Helmholtz maintains, by some other cause? Yet there are some further points in evidence which are of significance, and lend additional weight to the proofs already adduced.

Beats behave like primary impulses in the following respect, that when they come with a frequency between 32 and 128 per second, they may be heard, according to circumstances, either discontinuously or blending into a continuous sensation.

It has been objected that, whereas beats imply interference between two separate modes of vibration arising in two separate organs, combination-tones, whether summational, or differential, or any other, must take their origin from some one organ or portion of vibratile matter vibrating in a single but more complex mode. To this objection an experimental answer has been returned by Dr. Kœnig in the following way. He takes a prismatic bar of steel, about 9 inches in length, and files it to a rectangular section, so as to give, when it is struck at the middle of a face to evoke transversal vibrations, a sound of some well-defined pitch. By carefully adjusting the sides of the rectangular section in proper proportions, the same steel bar can be made to give two different notes when struck in the two directions respectively parallel to the long and short sides of the rectangle. A set of such tuned steel bars are here before you. Taking one tuned to the note $ut_6 = 2048$, with $re_6 = 2304$, Dr. Kœnig will give you the notes separately by striking the bar with a small steel hammer when it is lying on two little bridges of wood, first on one face, then on the other face. If, now, he strikes it on the corner, so as to evoke both notes at once, you immediately hear the strong boom of $ut_3 = 256$, the inferior beat-tone. If Dr. Kœnig takes a second bar tuned to ut_6, and $si_6 = 3840$, you hear also ut_3, this time the superior beat-tone. If he takes a bar tuned to ut_6 and the 11th harmonic of ut_3 (in the ratio 8 : 11), you hear the two beat-tones sol_4 and mi_5 (in ratios of 3 and 5 respectively) precisely as you did when two separate forks were used instead of one tuned bar.

Dr. Kœnig goes beyond the mere statement that beats blend to a tone, and lays down the wider proposition that any series of maxima and minima of sounds of any pitch, if isochronous and similar, will always produce a tone the pitch of which corresponds simply to the frequency of such maxima and minima. A series of beats may be regarded as such maxima and minima of sound; but there are other ways of producing the effect than by beats. Dr. Kœnig will now illustrate some of these to you.

If a shrill note, produced by a small organ-pipe or reed, be conveyed along a tube, the end of which terminates behind a rotating disk pierced with large, equidistant apertures, the sound will be periodically stopped and transmitted, giving rise, if the intermittences are slow enough, to effects closely resembling beats, but which, if the rotation is sufficiently rapid, blend to a tone of definite pitch. Dr. Kœnig uses a large zinc disk with 16 holes, each about 1 inch in diameter. In one set of experiments this disk was driven at 8 revolutions per second, giving rise to 128 intermittences. The forks used were of all different pitches from $ut_3 = 256$ to $ut_7 = 4096$. In all cases there was heard the low note ut_2 corresponding to 128 vibrations per second. In another series of experiments, using forks ut_2 and ut_3, the number of intermittences was varied from 128 to 256 by increasing the speed, when the low note rose also from ut_2 to ut_3.

From these experiments it is but a step to the next, in which the intensity of a tone is caused to vary in a periodic manner. For this purpose Dr. Kœnig has constructed a siren-disk (Fig. 1), pierced with holes arranged at equal distances around seven concentric circles; but the sizes of the holes are made to vary periodically from small to large. In each circle are 192 equidistant holes, and the number of maxima in the respective circles was 12, 16, 24, 32, 48, 64, and 96. On rotating this disk, and blowing from behind through a small tube opposite the outermost circle, there are heard, if the rotation is slow, a note corresponding to the number of holes passing per second and a beat corresponding to the number of maxima per second. With more rapid rotation two notes are heard—a shrill one, and another 4 octaves lower in pitch, the latter being the beat-tone. On moving the pipe so that wind is blown successively through each ring of apertures, there is heard a shrill note, which is the same in each case, and a second note (corresponding to the successive beat-tones) which rises by intervals of fourths and fifths from circle to circle.

These attempts to produce artificially the mechanism

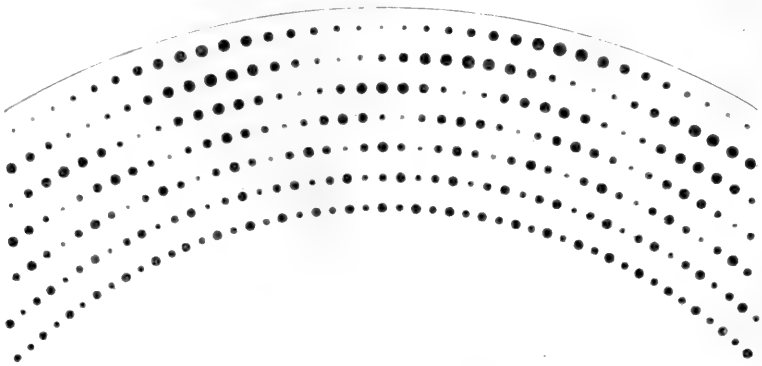

FIG. 1.

of beats were, however, open to criticism; for in them the phase of the individual vibrations during one maximum is the same as that of the individual vibrations in the next succeeding maximum; whereas in the actual beats produced by the interference of two tones the phases of the individual vibrations in two successive maxima differ by half a vibration; as may be seen by simple inspection of the curves corresponding to a series of beats. When this difference was pointed out to Dr. Kœnig, he constructed a new siren-disk (Fig. 2), having a similar series of holes of varying size, but spaced out so as to correspond to a difference of half a wave between the sets. With this disk, beats are distinctly produced with slow rotation, and a beat-tone when the rotation is more rapid.

Finding this result from the spacing out of apertures to correspond in position and magnitude to the individual wavelets of a complex train of waves, it occurred to Dr. Kœnig that the phenomena of beats and of beat-tones might be still more fully reproduced if the edge of the disk were cut away into a wave-form corresponding precisely to the case of the resultant wave produced by

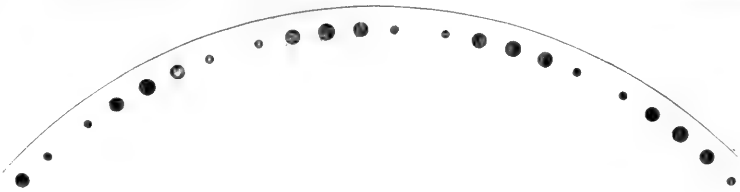

FIG. 2.

the composition of two interfering waves. Accordingly, he calculated the wave-forms for the cases of several intervals, and, having set out these curves around the periphery of a brass plate, cut away the edge of the plate to the form of the desired wave. Two such wave-disks, looking rather like circular saws with irregular teeth, are depicted in Figs. 3 and 4. These correspond to the respective intervals 8 : 15 and 8 : 23. A number of such

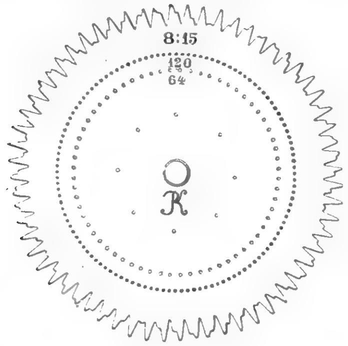

FIG. 3.

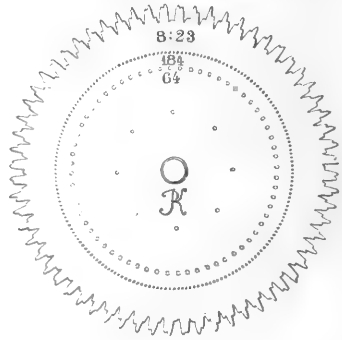

FIG. 4.

wave-disks corresponding to other intervals lie upon the table; these two will, however, suffice. In the first of these the curve is that which would be obtained by setting out around the periphery a series of 120 simple sinusoidal waves, and a second set of 64 waves, and then compounding them into one resultant wave. In order to permit of a comparison being made with the simple component sounds, two concentric rings of holes have been also pierced with 120 and 64 holes respectively. Regarding these two numbers as the frequency of two primary tones, there ought to result beats of frequency 8 (being the negative remainder corresponding to the superior beat). An interior set of 8 holes is also pierced, to enable a comparison to be made. To experiment with such wave-disks they are mounted upon a smoothly running whirling-table, and wind from a suitable wind-chest is blown against the waved edge from behind, through a narrow slit set radially. In this way the air-pressures in front of the wave-edge are varied by the rush of air between the teeth. It is a question not yet decided how far these pressures correspond to the values of the ordinates of the curves. This question, which involves the validity of the entire principle of the wave-siren cannot here be considered in detail. Suffice it to say that for present purposes the results are amply convincing.

The wave-disk (Fig. 3) has been clamped upon the whirling-table, which an assistant sets into rotation at a moderate speed. Dr. Kœnig blows first through a small pipe through one of the rows of holes, then through the other. The two low notes sound out separately, just a major tone apart. Then he blows through the pipe with a slotted mouth-piece against the waved edge; at once you hear the two low notes interfering, and making beats. On increasing the speed of rotation the two notes become shrill, and the beats blend into a beat-tone. Notice the pitch of that beat-tone: it is precisely the same as that which he now produces by blowing through the small pipe against the ring of 8 holes. With the other wave-disk, having 184 and 64 holes in the two primary circles, giving a wave form corresponding to the interval 8 : 23, the effects are of the same kind, and when driven at the same speed gives the same beat-tone as the former wave-disk. It will be noted that in each of these two cases the frequency of the beat-tone is neither the difference nor the sum of the frequencies of the two primary tones.

To be continued.)

DR. HENRY SCHLIEMANN.

THE death of Dr. Schliemann comes on his friends not only as a sorrow but as a surprise, for though he had tried his constitution, his strength was so great that it seemed equal to many more labours. He was essentially a self-made man, not merely as the architect of his own fortunes, but as having at an early age deliberately adopted certain purposes in life, and having acomplished them with astonishing success. These deliberate purposes made his career brilliant, and his character manly and sturdy.

In the preface to "Ilios" (1880) Schliemann gives a sketch of his early life and his excavations which reads like a romance. Before he was ten years old, he had made up his mind that the mighty walls of Troy could not have entirely disappeared, but must have been only buried by the dust of ages, and that he would himself some day bring them to light. But a romantic boyhood ended in a bitter struggle with poverty, until at one time he had to sell his last coat, and after shipwreck arrived at Amsterdam a penniless outcast. Obtaining there a post worth £32 a year, he spent the half of that sum on living, and the other half on self-education, his dinner costing him twopence, and a fire being an unknown luxury. By sheer business talent he rose from this poverty to great wealth; but this has been done by hundreds of uninteresting men: the interesting thing about Schliemann is that he never looked on wealth save as a means for accomplishing his darling purposes. While never ceasing to pray that some day he might have the happiness of learning Greek, he began on modern languages, which he mastered one after another in an incredibly short space of time, learning not merely to read, but to write and speak fluently, Swedish, Polish, Russian, Arabic, and many other tongues.

In 1871, he began his career as an explorer by an attack on the hill of Hissarlik, where he expected to find the remains of the Troy of his early dreams. In the art of excavation he seems to have had no teacher, and there can be no doubt that he has opened a new era in that art through his scientific genius. Literary genius may be erratic and incalculable, but genius works in science through clear discernment of means and by infinite pains. Schliemann's method was simple—to remove all the earth of a site and pass it through a sieve, taking care that, though hundreds of hands were at work, every one worked as an immediate organ of his own intelligence and design. The quality of insight came in principally in the choice of sites.

Splendid as were the results of Schliemann's excavations at Hissarlik, at Mycenæ, and at Tiryns, both as regards the recovery of antiquities, and as regards the advancement of knowledge, scholars recognize that he was not to be followed in his interpretation of his own discoveries. His individuality was too strongly marked, his imagination too fervent, to allow him to walk safely in the narrow ways of archæological science. And as a man who was born a fighter, and thoroughly carried out the old rule as to loving one's friends and hating one's enemies, he could not be impersonal in the choice of theories. To the judgment of his allies he often gave way with a delightful simplicity and modesty, but to attack he was impervious. One of his most interesting appearances in London was when he came in hot haste from Athens, accompanied by Dr. Dörpfeld, at the invitation of the Hellenic Society, to meet in open debate the objections, which he characteristically called "calumnies," which some archæologists had brought forward against his theory in regard to the prehistoric palace at Tiryns. Though Schliemann was a decided believer in Providence, there was in him an immense force of tough old Teutonic heathenism.

Yet he was a man of the world, and cosmopolitan in a sense in which few can claim to be so, for in almost any country he could have made himself at home as an active citizen. His ideal was Greece, and he succeeded in a very difficult task by finding in modern Greece the materials for a splendid ideal, when worked up with traditions of ancient glory. In this respect he was a greater poet than Byron, who spoke of some modern Greeks as "craven crouching slaves." Athens has indeed good reason for the gratitude which has assigned him a public grave at Colonus. At Athens he will leave a great gap. His palace, reflecting in every corner his career and his enthusiasms, was a place where the most open hospitality was accorded to men of all nations. In the living-rooms were Homeric texts; the servants bore high-sounding Greek names; the basement rooms were full of the spoils of Troy; while on the summit stood replicas of celebrated Greek statues. The host poured forth the simplicity of his heart and the overflowings of his enthusiasm, talking with an unconventional plainness sometimes disconcerting to Western ladies. Not even Madame Schliemann, long as she has shared her husband's labours and pursuits, can fill the blank which he has left. All archæologists must regret that his purposes of further excavation at Hissarlik, in Crete, and elsewhere, have dropped, or at any rate must be carried out by others who have not his marvellous power of finding valuable remains which others have failed to find.

THE METEORITE OF OSCHANSK.

A METEORITE which has lately been added to the collections of the Natural History Museum of Paris is described in *La Nature* by M. Stanislas Meunier; and by the courtesy of the editor of that journal we are enabled to reproduce the figures by which the article is illustrated. The meteor, of which this is a fragment, fell in Russia, on August 18 (30), 1887. Before it fell it was seen by various persons in the south-western part of the Government of Perm, and in the Government of Viatka—principally in the districts of Perm, Oschansk, Kungur, Osoo, and Sarapul. Between Perm and Oschansk, according to an inhabitant, it appeared about 12.30 p.m. in a clear sky, leaving behind it an almost horizontal train of great brilliancy. Detonations were heard, resembling a discharge of musketry rather than thunder. A little afterwards it fell in a shower of incandescent stones, which buried themselves more or less deeply in the earth. They were very numerous, and weighed from one to 330 kilogrammes. Fig. 1 represents the meteor as it was seen by M. Selivanof, a professor of the seminary of Perm. This observer writes:—

"On August 18, a little before one o'clock p.m., I returned to the seminary. The weather was calm, and the sky covered with small fleecy clouds. Just as I was about to cross the threshold, I happened to look towards the south, and saw a brilliant body like a shooting-star, or, rather, like a piece of iron glowing at the forge, gliding from east to west in a direction almost horizontal or slightly inclined towards the earth. The meteor made scarcely more noise than a rocket, and at first I believed it was one. Its course was sufficiently rapid, and during two or three seconds I followed the bolide over the space of a small number of degrees. It left a luminous train, which was very rapidly extinguished. Perhaps this train resulted simply from the persistence of the luminous impression upon the retina. The case, however, was otherwise with a pale nebulous band, which persisted about five minutes."

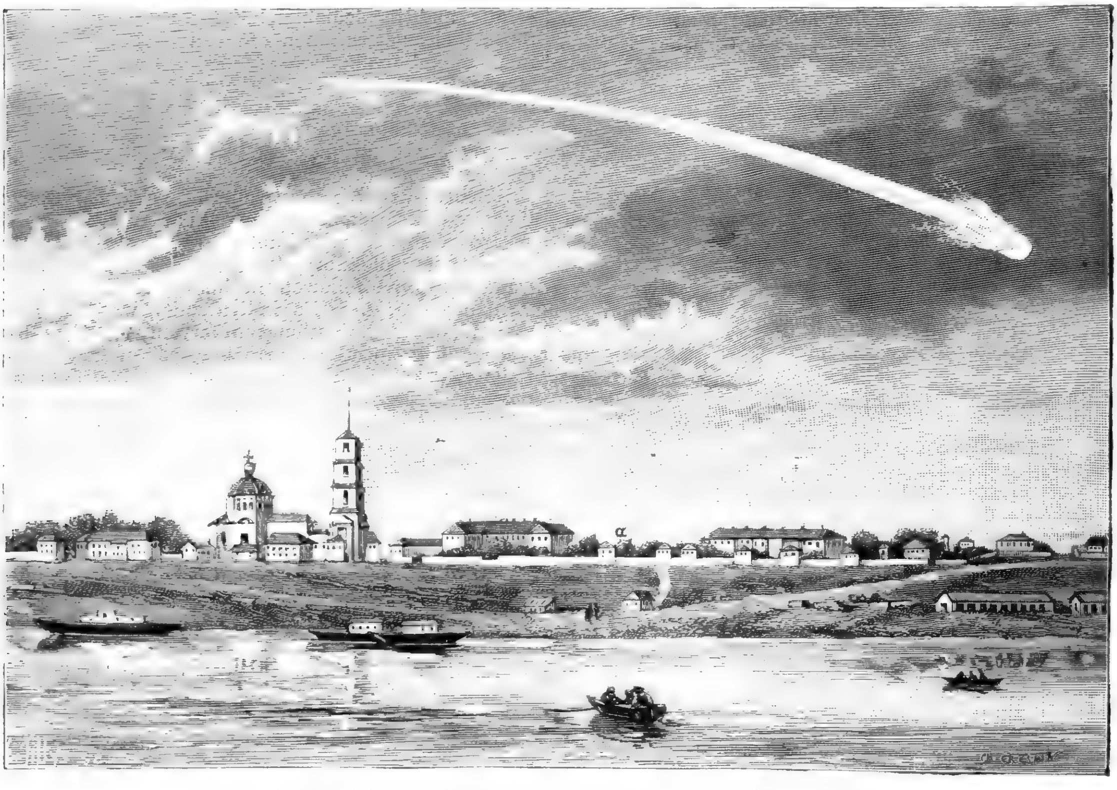

Fig. 1.—Passage of the meteorite of Oschansk, above Perm *a*, the point of observation.

The majority of the meteorites brought by this fine meteor have certainly been lost. Only six of them have been found—five at Oschansk, one at Tabor. At the moment of the fall, M. Nagibine was in a street of Oschansk, and heard the noise which announced it. About half a minute after the cessation of this noise, he observed a blackish stone which hissed through the air as a cannon-ball might have done. Several workmen ran and found the meteorite at the bottom of a hole—about 50 centimetres deep—which it had hollowed in the ground. It was as large as a child's head, and was still hot; it weighed 1·790 kg.

At Tabor the phenomenon was noticed by two peasants who were working in a field. Surprised by the detonations and the rumbling sound, they looked up, and saw the bolide, of a dark red colour, followed by a white smoke, which the wind agitated; and sending forth an odour of sulphur (Fig. 2). The mass seemed to be at a height of about 200 metres, and by the shock of its fall raised a column of dust. One of the peasants, who was mounted on a corn-rick, was thrown to the ground by the atmospheric disturbance. At the place where the stone fell they found a hole 4·20 metres deep, 2·10 metres wide (Fig. 3). The stone was too hot to be removed immediately. Next day it was taken out in fragments, one of which weighed 98 kilogrammes, the others from 100 grammes to 11 kilogrammes. There were about 82 kilogrammes of *débris*. The entire weight of this single stone is estimated at 328 kilogrammes.

From information furnished by the observers it is concluded that the bolide moved from 10° to 15° from

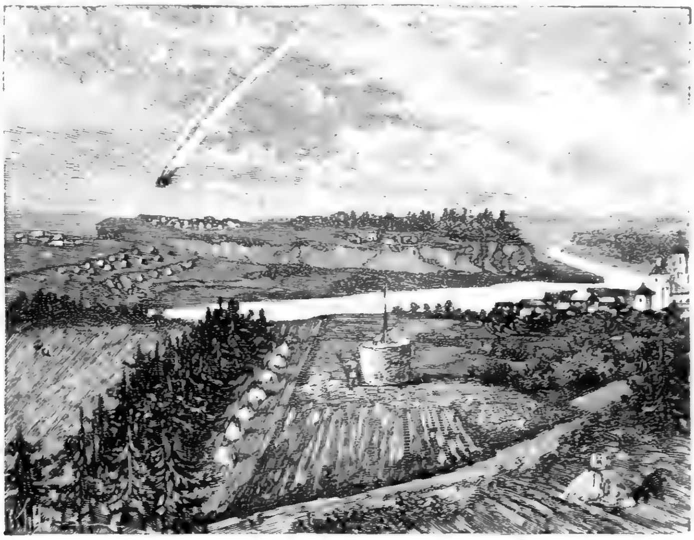

FIG. 2.—Passage of the meteorite at Tabor.

the east towards the south, and that, from the point of observation in the field, the angle of the fall appeared to be about 55° above the horizon.

Another stone, which has not been found, fell into the River Kama, at Tabor. A forester who was near the spot, says that the banks of the river trembled, and that the water, after having been thrown up in a high column, continued to bubble for a long time. The air was so violently agitated that a troop of 50 or 60 horses, which were drinking at the river, were thrown to the ground.

When the fragments found at Tabor were pieced together, the stone presented the form of a polyhedron with

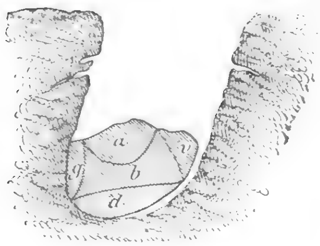

FIG. 3.—Meteorite of Tabor, after its fall. *a*, its largest fragment (98 kg.); *b*, part taken away by the public; *v*, grey part; *g*, fragment weighing two kilogrammes; *d*, small fragments.

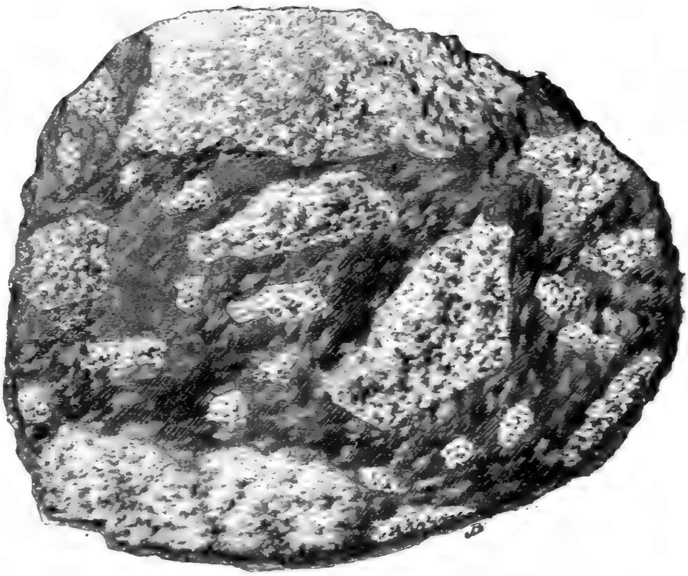

FIG. 4.—Fragment of the meteorite of Oschansk (in the Museum of Natural History, Paris).

angles very much blunted. It was enveloped in the usual black crust, but this was exceptional in presenting flaws as big as a pea, or even larger.

Fig. 4 represents the appearance of the specimen in the Paris Museum. M. Stanislas Meunier has made it a subject of chemical and microscopical study, which has led him to the conclusion that the meteorite of Oschansk belongs to a lithological brechiform type, which he described twenty years ago under the name of "Canellite." To the same type belonged, among others, the meteorites of La Baffe (Vosges), September 13, 1842; of Assam (India), 1846; of Canellas (Spain), May 14, 1861; of

Feid-Chair (Algeria), August 16, 1876. The stone consists of fragments of two very oolithic rocks, one called "Limerickite," of a dark violet colour, the other, called by M. Meunier "Montréjite," quite white. From the juxtaposition of different rocks in this as in some other meteorites, M. Meunier argues that, in the *milieu* where these stones are formed, the general geological conditions must be analogous to those which exist on the earth.

NOTES.

THE general meeting of the Association for the Improvement of Geometrical Teaching is to be held at University College, Gower Street, on Saturday, January 17. At the morning sitting (10.30 a.m.), the reports of the Council and Committees will be read, and the new officers will be elected. On the conclusion of the elections Miss Wood will read a paper "On the use of the term 'Abstract' in Arithmetic." After an adjournment for luncheon at 1 p.m., members will re-assemble for the afternoon sitting (2 p.m.). Papers will be read by Prof. Minchin, on "Another Voyage to Laputa"; by Mr. E. T. Dixon, on "The Foundations of Geometry"; and by Mr. E. M. Langley, on "Some Notes on 'Statics and Geometry.'"

PROF. RUDOLF VIRCHOW will reach his seventieth birthday on October 13. It has been decided that the occasion shall be commemorated by the striking of a large gold medal in his honour.

SEVERAL men of science were included in the list of New Year honours. A baronetcy was conferred on Dr. Richard Quain, and Prof. George Humphry, Cambridge. Prof. Ball Director of the Museum of Science and Art, Dublin, was made a C.B.; Dr. Theodore Cook, Principal of the College of Science, Poona, became a Companion of the Most Eminent Order of the Indian Empire; and Mr. Frederick McCoy, C.M.G., Professor of Natural Science in the University of Melbourne, was promoted to be an ordinary member of the second class, or Knight Commander of the Most Distinguished Order of St. Michael and St. George.

THE memorial concerning the ancient monuments of Egypt, which was lately presented to Lord Salisbury, has been so far successful. It is to be forwarded to H.M.'s Agent and Consul-General at Cairo, for presentation to the Egyptian Government; and Sir E. Baring will be instructed to state that if an official inspector is appointed the question of his nationality will not be considered important, the only desire of the British Government being that adequate steps shall be taken "to preserve the monuments from further destruction or mutilation."

WE regret to have to record the death of Mr. John Marshall, F.R.S., President of the General Medical Council, and Professor of Anatomy to the Royal Academy. He died on January 1, at the age of seventy-two. Mr. Edward Bellamy, whose studies were akin to those of Mr. Marshall, died on the 4th inst. after an illness of only three days. He had been for many year lecturer on artistic anatomy at the South Kensington School.

PROF. CASEY, F.R.S., Fellow of the Royal University of Ireland, died on January 3, at the age of seventy. He was an eminent mathematician, and much regret at his death has been expressed in Ireland.

A CIRCULAR letter from the Societa Italiana di Scienze Naturali of Milan, dated January 2, announces the death of their President, the Cav. Abate Antonio Stoppani, Professor of Geology in the R. Istituto Tecnico Superiore. The President died on New Year's Day, at the age of sixty-six.

PROF. W. J. STEPHENS, President of the Linnean Society of New South Wales, died on November 22, 1890. At the meeting of the Society on November 26, resolutions were passed, expressing high appreciation of his services and sympathy with his family.

MR. WILLIAM LANT CARPENTER, who died on December 23 last, was the eldest son of the late Dr. W. B. Carpenter. He was born in 1841, and educated at University College School and University College. At the age of eighteen he went to Bristol as chemist to Messrs. C. J. Thomas and Brothers, soap and candle manufacturers, in which firm he became a partner. Afterwards he gave up business, and settled in London, eventually becoming one of the managers of the School of Electrical Engineering in Hanover Square. For some time past he has been widely known, more especially in the north of England, as one of the most successful lecturers in connection with the Gilchrist Educational Trust and the University Extension movement. In 1885 he brought out "A Treatise on the Manufacture of Soap and Candles, Lubricants, and Glycerin"; and he contributed a few papers on kindred subjects to the Journal of the Chemical Society, and the Proceedings of the British Association. Under the title "Energy in Nature" he published in 1883 a popular exposition of the doctrine of the conservation of energy, being the substance of six lectures delivered for the Gilchrist Educational Trust two years previously; and in conjunction with the late Prof. Balfour Stewart he contributed some papers to the Proceedings of the Royal Society on the periodic changes of sun-spots, and their connection with terrestrial and magnetic phenomena.

ON January 2 the Institution of Civil Engineers reached its seventy-third anniversary. The numbers of the various classes now on the books comprise 1700 members, 2880 associate members, 427 associates, 19 honorary members, and 927 students—together 5953.

THE Calendar of the Department of Science and Art for the year 1891 has been issued.

A SPECIAL Commission has been for some years established at Trieste by the Austrian Government for the oceanographic investigation of the Ionian and Adriatic Seas. During the past year the transport *Pola* has been set apart for the study of the sea-bottom, currents, temperature, &c., of the Adriatic, and has obtained important results. At a depth of 2000 metres abundance of a green Alga, *Halosphæria viridis*, was found.

THE marine laboratory of the Johns Hopkins University is to be opened next spring.

A PHOTOMICROGRAPHIC laboratory has been opened at Rimini by Count R. Sernagiotto, for the preparation and publication of photographic reproductions. Among the microphotographs already issued, *Notarisia* mentions, as of remarkable clearness and beauty, one of *Pleurosigma angulatum*, 5000 diams., of *Bacillus radiciformis*, 1000 diams., and a tangential section of the stem of the vine, 75 diams.

THE American National Educational Association will hold its next meeting at Toronto in July. Many teachers of the Dominion have become members, and *Science* says that "they will meet in Toronto in full force, and will prepare an exhibit giving a complete view of Canadian systems of education."

UNDER the auspices of the Penzance Natural History and Antiquarian Society and the Committee of the Penzance Library, a fund is being raised for the purpose of erecting a suitable monument or tombstone in Penzance Cemetery, as a memorial of the late Mr. John Ralfs, who died July 14, 1890. Subscriptions should be sent to Mr. W. Bolitho, Jun., Penzance, Treasurer of the Ralfs Fund.

DR. JULIUS WORTMANN, one of the editors of the *Botanische Zeitung*, has been appointed Director of the physiological experimental station of the Royal Institution for instruction in fruit- and vine culture at Geisenheim on the Rhine.

THE Trustees of Columbia College, U.S.A., have appointed as Curator of their Herbarium Dr. Thos. Moring, who has just returned from a botanical exploration of southern South America with very large and valuable collections.

THE Horace Mann School, Boston, Mass., recently celebrated its twenty-first anniversary. The Hon. Gardiner G. Hubbard delivered an interesting address on the occasion, sketching the history of the articulating system for the deaf in America. In 1860, Mr. Hubbard's daughter, who was then four years old, lost her hearing through a severe illness. Mr. Horace Mann and Dr. Howe had been studying the various methods of educating the deaf in Europe, and had reported in favour of the oral system which had for some time been practised in Germany. Mr. Hubbard therefore consulted Dr. Howe, who recommended that the child's relatives should talk to her, and teach her to recognize the spoken words of their lips. He especially urged that they should not have recourse to signs, and that they should persistently refuse to understand them. The plan was tried, and the result was so successful that a little school for the deaf, with Miss Rogers as teacher, was opened at Chelmsford in 1866. By and by a charter was granted, and the school was transferred to Northampton. The system attracted the attention of Mr. Dexter S. King, and through his efforts a school was started in Boston in 1869. This institution was afterwards called the Horace Mann School, and its success was to a large extent due to the intelligence and enthusiasm of Miss Fuller and Miss Bond, to whose work Mr. Hubbard, in his address, did ample justice. Now the advantages of the oral system are widely recognized, and, as Mr. Hubbard pointed out, the influence of the Horace Mann School has been felt in England as well as in many different parts of the United States.

IN connection with a meeting of the American Electric Light Association, which is to be held at Providence in February, there will be an exhibition of electrical apparatus and appliances, especially such as are used in the furnishing of light and power. This meeting will practically mark the close of the first decade of "electric lighting commercially." It has been suggested, therefore, as we learn from *Science*, that efforts should be made to show the progress in the art by the exhibition of the earlier forms of apparatus and appliances, along with those embodying the latest improvements.

AT the meeting of the French Cremation Society on December 13, an able address on the subject of cremation was delivered by M. Fréderic Passy, member of the Institute. Dealing with the common objection that incineration would facilitate poisoning, he urged that the traces of vegetable poisons vanish rapidly, and that if mineral poisons were used most of them could be detected in the ashes. Moreover, he insisted that there are poisons the presence of which in a human body does not necessarily prove that a crime has been committed; and that if cremation were generally adopted greater care would be taken to determine the precise causes of death. That there is in many minds a strong prejudice against cremation he admitted; but this he attributed to the influence of ancient custom. Irresistible evidence, he maintained, showed that the existing system cannot but be injurious to public health.

THE Administration of the schools of Caucasia is continuing the publication of the excellent linguistic works of Baron Uslar. The fourth volume, which is now out, contains his study of the Lakh language, as well as (in an appendix) his letters to Prof. Schiepner and a Kazy-kumukh alphabet.

THE British Museum (Natural History) has issued the third edition of a Catalogue containing a list of all the subjects of which moulds and store-casts have been prepared for the purpose of supplying museums, and the public generally, with copies of the most striking objects in the collection that will admit of being moulded without injury. The casts are chiefly reproductions of specimens of fossils in the Department of Geology. The prices (revised to date) have been approved by the Trustees.

AN excellent number completes the third volume of the *Internationales Archiv für Ethnographie.* Dr. P. Schellhas, of Berlin, contributes (in German) a most careful paper embodying the results of comparative studies in the field of Maya antiquities. These antiquities he divides into three classes—architectural remains; Maya MSS.; and smaller objects. The latter class has been greatly enriched by the Yucatan collection now in the Berlin Museum für Völkerkunde. Dr. J. H. Spitzly, military surgeon in the Dutch West Indian army, brings together some instructive notes (in English) on three stone adzes from Surinam (Dutch Guiana), and on eight stone implements from the islands of St. Vincent and St. Lucia. A paper (in German) on old Mexican and South American throwing-sticks is contributed by Dr. H. Stolpe, of Stockholm; and Dr. J. D. E. Schmeltz, Director of the Leyden Ethnographical Museum, offers (in German) various facts and suggestions relating to the ethnography of Borneo. The illustrations, as usual, are remarkably good.

WE have received the volume of Records of the meeting of Russian Naturalists and Physicians which was held at the beginning of this year at St. Petersburg. It is a well printed octavo volume of about 1000 pages, with several engravings and maps, and it is sold at the extremely moderate price of five roubles. It contains the proceedings of all the meetings, and abstracts of the chief papers read, or the papers themselves; thus giving a series of most valuable contributions and notes in mathematics and astronomy, physics, chemistry, botany, zoology, geology, geography and anthropology, scientific agriculture, and scientific medicine. Some of the papers are very elaborate.

AN earthquake in Northern California, on January 2, is reported by Prof. Holden, of the Lick Observatory, to have been the most severe experienced in that district since 1868. The ceilings of the Observatory were cracked, the plaster falling to the floor. The large equatorial telescope is, however, believed to be uninjured.

LIEUT. J. P. FINLEY has published his long-promised storm-track, fog, and ice charts of the North Atlantic Ocean, in a quarto atlas. Part i. consists of track-charts for each month; these form a very tangled skein, but the *general* drift of the storms can be clearly seen: the majority of them pass to the north-west of the British Isles. Part ii. consists of 13 charts representing the storm frequency by shaded areas. A careful study of these charts will materially assist shipmasters to determine the general locality and frequency of storms in different months. If the main object were safety instead of speed, a more southerly route than the "lanes" generally followed would be preferable. In voyages *from* America vessels sail more or less with the prevailing direction of the wind, and *vice versâ.* The fog and ice charts show the average probable and extreme eastern and southern limits at which these may be encountered in each month. Icebergs are most frequently met with from July to September inclusive; from November to June the drift of the bergs southwards is impeded by ocean ice in the friths.

THE *Bulletin Mensuel* of the Zi-ka-Wei Observatory (near Shanghai) contains a discussion of the monsoons of the Yang-tse-Kiang from the observations at the stations of the maritime customs established from the entrance of that river as far as Hankow. The results are given in the form of wind-stars, which show that at the mouth of the river the influence of the two monsoons is sharply marked: the winter monsoon blows from between north-west and north-east, the north-west winds being most prevalent, while the summer monsoon blows from between south and south-east. After leaving the mouth the distinction is not so plainly marked; the prevalent winds tend more to the north-east in winter, and in summer more to the east and even north-east.

THE new Russian *Meteorologitcheskiy Sbornik*, published by the Russian Academy of Sciences, to the first volume of which we referred the other day (p. 183), contains Russian translations and Russian originals of papers published in German and French in vol. xiii. of the *Repertorium für Meteorologie*. The two publications will be parallel, under the Director of the Central Observatory, H. Wild.

IN a report to the Foreign Office, recently published, Colonel Stewart, the British Consul-General at Tabreez, calls attention to the curious system of lakes in that region, situated at a great elevation above the sea-level. These are the lake of Urumia, situated 4100 feet above the sea, Lake Van, and the Guektcha lake. Lake Van is in Turkish territory and the Guektcha lake in Russian territory, though both are near the bottom of the Persian province of Azarbaijan, in which is situated the lake of Urumia, the largest and most important. It is 84 miles long and 24 miles broad, and is probably the saltest piece of water on earth, being much salter than the Dead Sea. The water contains nearly 22 per cent. of salt. Its northern coasts are encrusted with a border of salt glittering white in the sun. It is said that no living thing can survive in it, but a very small species of jelly-fish does exist in its waters. Many streams pour down from the Kurdish mountains which border Turkey, and render the country between them and the lake of Urumia very green and fertile. This part of the country looks more like India than Persia, but the climate is severe in winter. The whole country being situated from 4000 feet to 5000 feet above ocean level, the snowfall in winter is great. At night in winter the thermometer falls frequently below zero of Fahrenheit, but in the day-time it rises considerably, generally reaching 28° or 30°, and this with a bright sun overhead. Many people are frozen to death on the roads in winter while crossing the various passes. The winter climate may be compared to that of Canada, but the summer approaches that of Northern India.

THE area under the administration of the Bengal Forest Department, according to its last Report, during 1889–90 consisted of 5195 square miles of reserved forest, 2239 square miles of protected forests, and 4034 square miles of unclassed State forest and waste lands, aggregating 11,468 square miles, which is 5½ per cent. of the total area of the province, viz. 193,198 square miles. The forests are, however, confined to the districts bordering on the sea, the sub-Himalayan tracts and the plateau of Central India, so far as it stretches into Chota Nagpore and Orissa. An area of 207 square miles was added to the reserves during the past year, and 25 square miles of protected forests in the Sunderbunds were farmed out for reclamation. The title of Government to existing reserves is being completed by a compliance with the requirements of the Act, and the inquiries incidental to these proceedings will also secure the record and protection of private easements. The special measures taken for the protection of forests from fires have been increasingly successful, 95 per cent. of the areas thus dealt with having escaped, in spite of the dryness of the season, against 72·9 per cent. in the previous year. The financial results of the past year show a net surplus of Rs. 3,78,454, against Rs. 3,08,738 in 1888–89.

TOADS have been observed by some persons to feed willingly on bees and even wasps; and M. Hiron-Royer, who has noticed the fact, says that *Hyla versicolor* is positively frantic about wasps. He has seen one prefer them to every other kind of food, and devour them eagerly, although the sting does sometimes bring the creature to temporary grief.

ONE of the last volumes of the *Mémoires* of the Kazan Naturalists (vol. xxii. 5) contains a most valuable work by P. Krotoff and A. Netchaieff, upon the geology of the Kama region, being the first part of a general description of that region which the Society intends to publish. The oldest geological formation of the region is that succession of red and grey sandstones and limestones, as well as of "variegated marls," which is considered as Permian by the Kazan geologists, and Triassic by other Russian explorers. The chief interest of the Lower Kama region is, however, in its Post-Pliocene deposits. They cover nearly the whole of the territory, and belong to two different series: the yellow loess-like sandy clays—containing the usual terrestrial shells (*Helix*, *Pupa*, *Succinea*, *Limnæus*, *Pisidium*, &c.), together with bones of Mammoth and Rhinoceros—and the Caspian deposits. The latter attain a quite unexpected development, as they are found in all the valleys, thus bearing unmistakable evidence of the former extension of gulfs of the Caspian Sea up the valley of the Kama (almost as far as its junction with the Vyatka) and its tributaries. Deposits, containing the undoubtedly Caspian species of *Adacna plicata*, *Cardium edule*, *Dreissena polymorpha*, and *Valvata piscinalis*, as well as teeth of fishes, reach the heights of from 530 to 540 feet above the sea-level; and their presence has been noticed on the Byelaya river as far as Angasyak, as also in the north of the Kama at the town of Laishev, and in the lower parts of the Mesha river. It is thus certain that a gulf of the Caspian Sea penetrated up the valley of the Volga and its tributaries as far as 55° 23′ of northern latitude, and that the upper parts of this gulf contained a water less salt than that of the Caspian Sea. It is very difficult to ascertain whether the deposits just mentioned belong to the later parts of the Pliocene period, or to the earlier parts of the Post-Pliocene, and Russian geologists are divided upon this point. But the Kazan authors point out the absolute identity of the fossil species of *Adacna*, *Cardium*, *Dreissena*, *Didacna*, and *Hydrobia*, with those now living in the Caspian Sea; while the discovery in a fossil state of a species of *Corbicula*, and Prof. Sintsoff's *Hydrobia novorossica*, which are not met with now in the Caspian Sea, is not considered as sufficiently proving the greater antiquity of the Kama deposits. Part of these deposits have been denuded by the rivers and mixed with the above-mentioned loess.

OUR ASTRONOMICAL COLUMN.

PERIHELIA OF COMETS.—In *Astronomische Nachrichten*, No. 3005, Dr. Holetschek discusses the apparent connection between the heliocentric longitudes of comet perihelia and the heliocentric longitude of the earth at the times of their perihelion passages. It is evident that any one comet appears brightest when its *perihelion* passage occurs at the same time as that of *perigee*. The possibility of discovering and observing comets decreases, therefore, with the increase of the arc contained between the heliocentric longitudes (l) of comet perihelia and the heliocentric longitude (L) of the earth during the perihelia.

Dr. Holetschek has tabulated the value of (l – L ± 180°) for every known comet, and the values obtained are as follows:—

(l – L ± 180°)	Number of elliptic comets.	Number of parabolic comets.	Total number with perihelion distances greater than 0·3.
0 to 30	16	90	106
30 ,, 60	10	45	55
60 ,, 90	3	46	49
90 ,, 120	2	26	28
120 ,, 150	—	21	21
150 ,, 180	—	22	22
Total ...	31	250	281

It will be seen that the majority of all the known comets have the longitude of their perihelion at a small angular distance from that of the earth. This grouping is especially well marked in the case of elliptic comets of short period. The following table exhibits the results found for comets with perihelion distances less than 0·3 times the mean distance of the earth from the sun:—

l – L	Number of parabolic comets.
0 to 60	19
60 ,, 120	10
120 ,, 180	7
Total ...	36

Another interesting result brought out by Dr. Holetschek's investigations is that the positive sign occurs with very nearly the same frequency as the negative sign in the angle l – L ± 180°. This indicates that the perihelion points, when reduced to the ecliptic, lie, with equal frequency, in front of and behind the earth.

Mr. W. E. Plummer points out, in this month's *Observatory*, that the cause of the abnormal distribution exhibited by comets whose orbits are greatly inclined to the elliptic has still to be explained.

GASEOUS ILLUMINANTS.

I.

THE autumn course of Cantor Lectures at the Society of Arts was delivered by Prof. Lewes, who, after discussing the nature of various gases capable of burning with luminosity, gave a review of the theories which have been advanced to explain the light-giving power of certain flames.

Sir Humphry Davy first propounded his theory that the cause of luminosity in ordinary flames was the incandescence of nascent carbon—a theory which was accepted as the true one until the researches of Dr. Frankland in 1868, on the effect of pressure on non-luminous flames, showed that, under certain circumstances never likely to arise in a gas-flame, luminosity might be due to other causes. Later observers have shown that luminosity in a flame is to a great extent affected by temperature. These factors, though of the greatest importance, do not affect the truth of the original theory.

In the Philosophical Transactions for 1817, Sir Humphry Davy says, while alluding to a paper published in one of the early numbers of the *Journal of Science and Arts*: "I have given an account of some new results on flame, which show that the intensity of the light of flames depends principally upon the production and ignition of solid matter in combustion."

This definition, however, has been gradually altered until it is more often stated that "the presence of solid particles suspended in the flame (or in immediate contact with the burning gas) is essential to its luminosity"—an idea which Davy never had, as is shown by him later in the paper defining flame as follows: "Flame is gaseous matter heated so highly as to be luminous;" and again: "When, in flames, pure gaseous matter is burnt, the light is extremely feeble." Moreover, he alludes to "common flames"—evidently meaning the flames of candles, lamps, or gas; in all of which cases I think it can be proved beyond a doubt that his theory, as expounded by himself, was perfectly correct.

On June 11, 1868, Prof. E. Frankland read a communication before the Royal Society, in which he described experiments which led him to doubt Sir Humphry Davy's theory. He points out that the deposit of soot formed when a cold surface is held in a gas or candle flame is not pure carbon, but contains hydrogen, which can only be got rid of by prolonged heating in an atmosphere of chlorine. Also that many flames possessing a high degree of luminosity cannot possibly contain solid particles. Arsenic burnt in oxygen gives a bright white light; yet as arsenic volatilizes at 180° C., and the arsenic trioxide forms at 218° C., it is evident that at the temperature of incandescence (which is at least 500° C.) there can be no solids, but simply vapours present in the flame; and for the same reason, the intense light resulting from the burning of phosphorus in oxygen cannot be explained by the solid particle theory. From these results, Dr. Frankland considers that "incandescent particles of carbon are not the source of light in gas and candle flames, but that the luminosity of these flames is due to radiations from dense but transparent hydrocarbon vapours;" and he further shows that non-luminous flames, such as that produced by carbon monoxide and hydrogen, can, when burning in an atmosphere of oxygen, be rendered luminous if the ordinary atmospheric pressure is increased to 10 atmospheres, so as to prevent or retard as far as possible expansion during combustion. From Dr. Frankland's experiments, there is no doubt that the luminosity of a flame is increased by pressing around it the atmosphere in which it is burning, and also that rarefaction has the opposite effect—a point also worked at by Davy; but his experiments do not show that incandescent particles of carbon are not the principal source of luminosity in a gas-flame. He also shows that, the higher the density of the vapours present in a flame, the more likely is it to be luminous.

In 1874, Soret attempted to demonstrate the existence of solid particles in a luminous hydrocarbon flame, by focussing the sun's rays on the flame, and examining the reflected light by means of a Nicol prism; but neither his research nor that of Burch, who repeated his experiments, using the spectroscope instead of the prism, showed more than that solid particles are present. Herr W. Stein, in considering Dr. Frankland's objections to Davy's theory, pointed out that the soot which is deposited from a candle or gas flame, and which Frankland looked upon as a condensed hydrocarbon, contains 99·1 per cent. of carbon and only 0·9 per cent. of hydrogen, which is about the quantity of hydrogen one would expect to be occluded by carbon formed under these conditions, and he also pointed out that if the soot were a heavy hydrocarbon condensed by a cold surface, cooling the vapour present in the flame, it ought to again become volatile at a high temperature, which it does not. The next steps in the controversy were the attempts made by Hilgard, Landolt, and Blochman, to trace the actions taking place in various flames by withdrawing the gases from different parts of the flame and determining their composition.

The experiments so made show that of the ordinary constituents of the gas the hydrogen is the first to burn, as one would expect from its relatively low igniting point and great rapidity of combustion. The burning of the carbon monoxide cannot be traced in the same way, as it is formed more rapidly (by the incomplete combustion of the marsh gas) than it burns, so that a steady increase in the proportion present takes place while the marsh gas steadily burns away, until a height of 1½ inches is attained, when its combustion becomes very rapid. Practically the illuminants do not undergo any change at first—indeed, they slightly increase in quantity from the decomposition by heat of some of the marsh gas into acetylene. They only begin to decompose at a height of 1½ inches above the orifice of the burner; and then burn rapidly in the highest part of the flame. Moreover, a most important fact to be noted is that at the height of 1½ inches there is a sudden rise in the quantity of carbon monoxide at the moment that the illuminating olefines begin to disappear—a result undoubtedly due to the action of the nascent ignited carbon on carbon dioxide.

The illuminants in the flame consist of various hydrocarbon gases and vapours which in the lower part of the flame are reduced by the heat to simpler hydrocarbons, and finally in the luminous zone become decomposed to methane and carbon; and it is the carbon in excessively minute particles which at the moment of liberation is heated to incandescence, and "principally" gives the light of the flame—the marsh gas originally present, and also that formed from the heavier hydrocarbons, adding its quota to the luminosity by still further decomposition during combustion, and finally becoming carbon dioxide and water. In 1876, Dr. Karl Heumann made a most important contribution to the theory of luminous flames in some papers published in *Liebig's Annalen*, in which he carefully went over the work of previous observers, and, by a large number of original experiments, proved that Davy's theory was correct, but that other causes also affected the degree of luminosity in a gas or candle flame.

In the ordinary atmospheric burner in which a mixture of coal gas and air burn with a non-luminous flame, it was supposed that the admixture of air, by supplying oxygen to the inner portion of the flame, caused immediate and complete oxidation of the hydrocarbons, without giving time for the liberation of carbon in the flame, and consequently luminosity. More modern researches, however, have proved this to be utterly wrong. The loss of luminosity is due to two causes—first, to the diluting action of the air introduced; secondly, to the fact that when a gas is so diluted, it requires a far higher temperature to break up the hydrocarbons present than when the gas is undiluted, and therefore the temperature which serves to liberate carbon and render the undiluted gas-flame luminous, is totally insufficient to do so in the diluted gas. Consequently the hydrocarbon burns to carbon dioxide and water without any such liberation, and hence with a non-luminous flame. The truth of this theory can be easily proved by the fact that diluting the gas with nitrogen, carbon dioxide, or even steam, serves to render it non-luminous, and therefore more rapid oxidation has very little or nothing to do with it, while the non-luminous flame can again be rendered luminous either by heating the mixture of air and gas just before combustion, or by heating the air with which the gas is diluted. This being so, it is evident that in the non-luminous flame we have the same hydrocarbon present as in the luminous flame; and anything that will tend to break them up, and liberate the carbon before the hydrocarbons are consumed, should again make the flame luminous.

That heat will do this has been already shown; but it can be demonstrated in a still more striking way. It is well known that chlorine gas and bromine vapour will both support the combustion of a gas containing much hydrogen, but that the combustion is very different from that of the same gas burning in air, as the chlorine or bromine, having no affinity for the carbon, combines with the hydrogen only, and deposits the carbon in clouds of soot; in other words, at the temperature of flame, chlorine will break up the hydrocarbons and liberate solid carbon. If now a small quantity of chlorine is led into the non-luminous Bunsen flame, it at once becomes luminous, proving conclusively that luminosity is due to solid particles of carbon liberated in the flame. Again, Heumann points out that a small rod held in the luminous flame becomes rapidly covered on its lower side with a deposit of soot; that is to say, the soot is present in particles in the flame, and the uprush of the gas drives it against the rod and deposits it there. If the soot were present in the flame, as Frankland supposed, in the state of vapour, and the rod merely acted by cooling and condensing it, the soot should be deposited on all sides of the rod; while a still further proof is, that if the soot existed as vapour in the flame, then, if the rod were heated to a high temperature, no soot should be deposited on it, whereas the soot deposits on a heated surface just as well as on a cool one.

It has been objected to the "solid particle" theory that, if it were true, solid carbon particles introduced into a non-luminous flame should render it luminous and make it look like an ordinary gas flame, whereas it simply gives rise to a cloud of sparks. But it must be remembered that the "nascent" carbon, as it is liberated from the decomposing hydrocarbons, is in the molecular condition, and has a very different degree of coarse-grainedness to any preparation of charcoal or lampblack we can make; and that, although our finest particle is a mass which takes so long to burn that it leaves the flames only partly consumed, and is projected into the air as a spark, the molecular particles of carbon are consumed as soon as they are rendered incandescent, and a steady luminosity, free from sparks, results. It is possible, however, to make the particles in a luminous flame roll themselves together, when they can be either deposited in a very coarse kind of soot, or be seen as glowing sparks and particles in the mantle of the flame. This can be done when two luminous flames are allowed to rush against each other or against a heated surface. Heumann also shows that the luminous mantle of a flame is not altogether transparent, and that the thicker the flame-layer, and the greater the number of solid particles contained in it, the less transparent does it become. If a non-luminous flame—say, hydrogen—is charged with the vapour of chromyl dichloride (CrO_2Cl_2), chromic oxide is produced; and this flame, which undoubtedly contains solid particles, is quite as transparent as the hydrocarbon flame. Finally, those flames which undoubtedly owe their luminosity to the presence of finely-divided solid matter produce characteristic shadows when viewed in sunlight; the only luminous flames which do not throw shadows being those which consist of glowing vapours and gases. Luminous gas flames, oil-lamp flames, and candle flames produce strongly-marked shadows in sunlight, and therefore contain finely-divided solid matter; and that this can be nothing but carbon is evident from the fact that all other substances capable of remaining solid at the temperature of the flames are absent.

From these considerations it is evident that Sir Humphry Davy's theory as propounded by himself is perfectly true as regards the ordinary illuminating flames.

In the second lecture, Prof. Lewes pointed out that, in the various analyses of illuminating gases, the heavy hydrocarbons are, as a rule, expressed as "illuminants," and were formerly considered to consist mainly of ethylene. This is an idea which the researches of the last few years have shown to be totally erroneous, as, besides ethylene, there is undoubtedly present benzene, propylene, butylene, and acetylene, and probably such members of the paraffin series as ethane, propane, and butane, while under certain circumstances, crotonylene, terene, allylene, and others, are present. The determination of the illuminants is therefore by no means the simple process one would imagine it to be from the directions given in most text-books on gas analysis.

The illuminants present in any given sample of coal gas depend upon (1) the kind of coal used, (2) the temperature at which it is distilled, and (3) the length of time the gas is in contact with the heated sides of the retort, as well as with the liquid products of the distillation.

Having dealt with this part of the subject at considerable length, Prof. Lewes went on to criticize the various methods of gas analysis, showing that all analyses of coal-gas have hitherto been founded on the idea that the "illuminants"—*i.e.* the heavy hydrocarbons responsible for the illuminating power—could be absorbed by fuming sulphuric acid, chlorine, or bromine. This, however, he said, is undoubtedly not the case. Mr. Wright has shown that, when coal gas has been treated with this acid, the residual gas still retains from 32 to 55 per cent. of its original luminosity; and although this may, to a certain extent, be owing to the methane, which at high temperature becomes slightly luminous, it is certain that a considerable percentage is due to the higher members of the paraffin series which are not absorbed by the acid, and which the methods of analysis usually employed utterly fail to detect. Indeed, given a gas containing any member of the paraffin series other than methane, the analytical results are not only incorrect, but misleading, as the percentages of hydrogen and methane present will be absolutely nullified by a very small quantity of the higher hydrocarbons.

All researches on the composition of coal gas point to the presence of ethane, and probably of higher members of the marsh gas series; while in carburetted gases they are undoubtedly present to a far higher extent. Ethane, propane, and butane have all been shown to be present in small quantities; and as ethane gives double, propane three times, and butane four times its own volume of carbon dioxide, it is evident that exploding with oxygen and taking the volume of carbon dioxide as representing marsh gas will undoubtedly give too high results with ordinary coal gas, while with a carburetted gas it will render the whole analysis useless. Moreover, the free oxygen is next absorbed, and the remainder taken as nitrogen; and the volume of gas after absorption by Nordhausen acid, less the marsh gas and nitrogen, is taken as representing the hydrogen in the gas. The result is that the hydrogen is always far too low, not only because the volume of marsh gas is too high, but because the residual nitrogen, having to bear the brunt of all the errors of analysis throughout some seven or eight absorptions, is also nearly always too high. These palpable errors in the quantity of marsh gas and hydrogen also render worthless the calculations of the carbon and hydrogen density of the gas, on which great stress has been laid by previous observers. On the whole, therefore, it is not to be wondered at that no relation has been discovered between the carbon and hydrogen density and the illuminating value of the coal gas.

The method of analysis which Prof. Lewes finds best is as follows:—

Two of Stead's apparatus are taken and placed with the entrance tubes end to end, and filled—one with distilled water saturated with air, and the other with clean pure mercury. The gas to be tested is collected in one of the Stead absorbing tubes, over water, so as to be saturated; it is then transferred over mercury in the eudiometer tube of the second apparatus, and measured and passed into sodic hydrate, in order to absorb the small trace of carbon dioxide to be found in the highly-purified London gas. When present in only small traces, the amount of carbon dioxide lost by water saturation cannot be detected. After the absorption of the carbon dioxide, the gas is run into the second apparatus, and the oxygen estimated by absorption with alkaline pyrogallate, which must be strong and fresh, containing about 25 grammes of pyrogallic acid dissolved in 50 grammes of sodic hydrate in 200 c.c. of water. It is absolutely essential that the solution should be fresh, as after some time it will evolve a considerable amount of carbon monoxide. The heavy hydrocarbons have now to be estimated; and inasmuch as benzene is one of the most valuable illuminants in the coal gas, it would be of great value if any absorbent could be found that would separate the benzene and ethylene series. Unfortunately this does not exist as far as is known; the usual absorbents having the following drawbacks:—(1) Nordhausen sulphuric acid, in which sulphur trioxide has been dissolved until it will solidify on cooling, absorbs both ethylene and benzene, and therefore cannot be used to separate them. (2) Fuming nitric acid is a good absorbent for both series. (3) Bromine water acts far more rapidly on ethylene than on benzene, but undoubtedly does absorb a considerable quantity of the latter if left long in contact with a mixture of the two. (4) None of the foregoing affect methane in diffused daylight. The nearest approximate result is obtained by treating the gas first with strong bromine water, but not leaving it too long in contact with it, and then removing bromine vapour over sodic hydrate—the absorption being taken as the ethylene series; while the benzene is absorbed by fuming nitric acid or saturated Nordhausen acid—acid fumes being removed in the sodic hydrate tube before measurement over water. After absorption with nitric acid gas, is run back into the eudiometer, and measured over water. It is then passed into an absorption tube filled with a fresh solution of ammoniacal cuprous chloride. This must not be used for more than six determinations of an ordinary coal gas containing (say) 3 to 6 per cent. of carbon monoxide, or 3 of a carburetted water gas, as, after much carbon monoxide has been absorbed, the solution has a tendency to again give up small quantities of the gas. The gas is now returned to the mercury eudiometer tube; and, after measurement, it is passed into an absorption tube containing ordinary paraffin oil (previously heated until everything that will distil at 100° C has gone off), which absorbs ethane, propane, butane, and a good deal of the methane. The residue is then washed and mixed with oxygen, which has itself been analysed, so that the percentage of nitrogen and foreign gases in it is known, and the mixture exploded over mercury. The carbon dioxide formed is estimated; and its volume *plus* the volume of gas absorbed by the paraffin gives the volume of gases in the methane series. A fresh portion of gas is now taken over mercury, and is exploded with excess of analyzed oxygen. The carbon dioxide is absorbed by sodic hydrate, and the oxygen by pyrogallate; and the residue will be the nitrogen—the hydrogen being determined by difference. In this way an analysis of South Metropolitan gas shows—

	Hydrogen		47·9	
Illuminants	Ethylene series	approx.	3·5	Total Hydrocarbons 45·6 per cent.
	Benzene series	approx.	0·9	
	Methane series	by paraffin	7·9	
		by explosion	33·3	
	Carbon monoxide		6·0	
	Carbon dioxide		0·0	
	Oxygen		0·5	
	Nitrogen		0·0	
			100·0	

In such an analysis, the lecturer remarked, no pretence was made that the exact percentage of each illuminant was given, but the total of the hydrocarbons is accurate; and their rough subdivision gave a far clearer insight into the characters of the gas than the more pretentious and more faulty analysis upon which it has been customary to argue. He said it must be clearly borne in mind that he only put forward this scheme of analysis to meet the need now rapidly arising for a method which would show whether ordinary coal gas enriched by cannel, coal gas carburetted with either gasoline or oil gas, or coal gas enriched by highly carburetted water gas, was being dealt with. In the first case, the ethylene and benzene series would be found well represented, while the carbon monoxide was low; in the second, the amount of hydrocarbons in the methane series would have become greater, and if oil gas had been used, a small increase in carbon monoxide might also be noticed; while the presence of carburetted water gas at once brought up the quantity of carbon monoxide, and the methane series became more important illuminants.

Prof. Lewes went on to show that the light-giving value of the hydrocarbons present in coal gas varies very greatly, the illuminating power increasing very rapidly with the number of carbon atoms in the molecule; and concluded by fully discussing the effect which the various diluents present in coal gas had upon its illuminating value.

(*To be continued.*)

ON THE ORBIT OF α VIRGINIS.

PROF. H. C. VOGEL has contributed a further discussion o the orbit of α Virginis (Spica) to the *Astronomische Nachrichten*, No. 2995. The following is a translation of the greater part of his paper:—

"After the periodical approach and retreat of this star, which was suspected from last year's observations, had been proved by some spectrographic observations made this year, an examination of the spectrum has been made at every favourable opportunity. So far, it has been possible to observe Spica on twenty-four evenings, thus affording material which allows its period to be determined with a greater degree of accuracy. Before communicating the results of the measurements of the photographs it will be necessary to preface a few remarks relative to the accuracy attainable.

"In No. 2896 of the *Astronomische Nachrichten* I detailed the first results which were obtained by means of the new spectrograph. The measurements were then made on some stars with spectra of the second class, and the increased accuracy given to these observations by the fact that the measurements were not made on the Hγ line only, but on some exceedingly sharp lines in the neighbourhood, has been fully confirmed by the now completed measurements of all the stars of the second and third class accessible to the Potsdam instruments.

"In the case of stars of class I.*a*, however, in which the Hγ line is more or less broad and fuzzy at the edges, and there are no other lines near it, greater difficulties than I at first expected opposed themselves to the satisfactorily exact measurement of their spectra. At one time I had the intention of making the measurements, not on the hydrogen line, but on the better defined lines of another metal, such as magnesium, which possesses a strong line at 448 μμ. I abandoned this intention, however, because by adopting this means a number of stars, in whose spectra the said line of magnesium is weak or invisible, must have been excluded.

"The absorption lines of hydrogen in star spectra show by their appearance the following four types:—

"(*a*) Dark lines, with somewhat undefined edges, *e.g.* Capella.

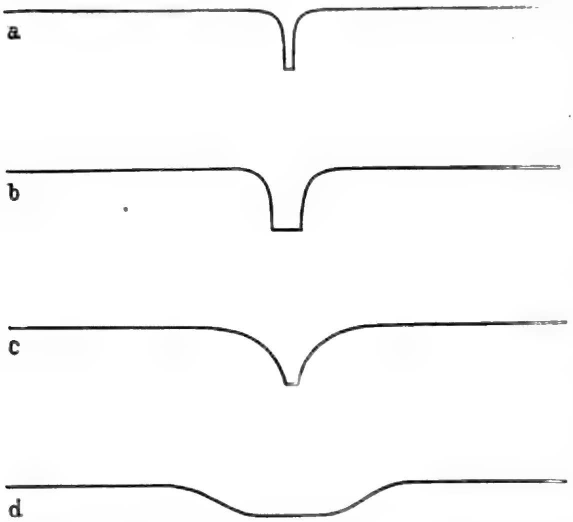
"(*b*) Broad dark lines, with somewhat undefined edges, *e.g.* Rigel.

"(*c*) Broad bands, gradually fading away, but with a more or less broad and well-defined maximum of intensity in the centre, *e.g.* Sirius.

"(*d*) Broad bands, undefined at the edges, without any remarkable maximum of intensity in the centre (Spica).

"The four types are graphically represented by the curves in the accompanying figure."

Prof. Vogel notes that when the maximum of intensity of the form (*c*) lies outside the line of comparison, the measurement of the distance between the two is attended with no special difficulties. When, however, the comparison line overlaps the line in the star spectrum under examination, or in the case of spectra of the form (*d*), special devices have to be used to determine the distance from the centre of the absorption line to the line of comparison, due to the star's motion in the line of sight. These methods



Diagrammatic representation of the appearance of hydrogen absorption-lines in four types of stellar spectra.

are described in the paper. The values obtained from measurements of photographs of the spectrum of Spica are shown in the following table :—

(+ = Recession ; − = Approach.)

With regard to these results, Prof. Vogel remarks :—

"If an early circular orbit be accepted, the observations here described allow of its possessing the form and period given by me in my first communication on α Virginis (*Sitzungsber. d. Akad. d. Wissensch. zu Berlin*, April 24, 1890), and it is shown that the period of revolution of 4·011 days is a safe one for a year's time, for the observations of this year are not in accordance with the epochs computed from the periods 3·967 and 4·055 days. Only a slight increase of the first period, 4·011 days, is indicated by the better reduction of last year's observations. The following elements have been deduced from the collected material :—

"Epoch t_0 (when the total orbital motion of the two components in the line of sight = 0) = 1890 May 4d. 10.50h. Potsdam mean time.

"Period p = 4·0134 days.

"Motion of the star system = − 2·0 geographical miles.

"Velocity in the line of sight, when the translation of the system has been deducted, = $12{\cdot}3 \sin\left(\frac{t-t_0}{p} 360°\right)$ geographical miles.

"The difference of four miles between the mean maximum positive and negative velocities might be explained by the hypothesis that the orbit of the star deviates considerably from a circle, and that the major axis of the ellipse is almost perpendicular to the line of sight. The observations, however, are not sufficient to decide this point, and as the motion of the system of − 2·0 miles (obtained by taking a circular orbit) corresponds to the average movement arrived at from the Potsdam observations, no foundation is afforded for any other hypothesis. . . . In consequence of my first communication on the orbit of α Virginis, Prof. Bakhuyzen has examined whether the Greenwich observations, notwithstanding their very slight accuracy, would afford data for a somewhat more exact determination of the period, as they extend over several years; and he has arrived at a period of 4 days 0·357 hours. From further communications I have learned from Prof. Bakhuyzen that his determination only rested on the comparison of some observations made at Greenwich in the years 1883 and 1886 with the Potsdam observations for the same years, but that no comparison of all the observations had been made. A somewhat more exact repetition of the calculation with respect to the times of observation, has, however, shown that, in consequence of the unaccustomed reckoning of time from midnight to midnight, which has been in use at Greenwich since 1885, Prof. Bakhuyzen had counted an observation as having been made on May 4, 1886, whereas according to astronomical reckoning it was made on May 3. When this oversight is corrected, the period obtained was 4 days 0·324 hours. I mention this, because Mr. Christie, in his annual report for 1890, has referred to the above-named period of 4 days 0·357 hours.

"I have examined the Greenwich observations somewhat carefully, and have come to the conclusion that they cannot be looked upon as sufficient to contradict the results of the Potsdam observations, and that no correction to the discovered period can be deduced from them with any certainty."

After a statement of the results of twenty-six observations of α Virginis made at Greenwich between 1876 and 1889, for motion in the line of sight, Prof. Vogel remarks :—

"If, taking twenty-six observations of α Virginis, the average result be counted, and no orbit introduced, it amounts to ±5·8 geographical miles. In the case of α Leonis it is ±4·4, of α Ophiuchi ± 6·7, and of α Aquilæ ± 6·5 (putting on one side the observations of 1874, 1875, and 1876, which give the value of ± 4·5 miles). Hence it is seen that, according to the Greenwich observations, there is no more cause for suspecting a periodical change of motion for α Virginis than for the other stars examined.

"If values are computed back to 1886 from the elements of the orbit previously given, a minimum of motion in the line of sight is obtained for 1886 April 30, 13·12 hours, and a maximum of negative motion on May 3, 13·36 hours, Potsdam time. These results agree very well with the Greenwich observations of those days. From the interval of time between the two minima in 1886 and in 1890, periods of 3·970 days and 4·058 days were obtained. With these two periods, and that best represented by the Potsdam observations, viz. 4·0134 days, I have computed some of the Greenwich observations according to the formula $12{\cdot}3 \sin \frac{t - t_0}{p} 360°$, after the translation of the system deduced from the Potsdam observations had been subtracted. It did not seem allowable to carry the reckoning any further back, as even the period of 4·0134 days may be doubtful in the third decimal place."

A comparison of nine observations made between April 1886 and May 1889 with calculated motions based on the assumed period of 3·970 days, gave a residual of ± 4·4 ; with the period 4·0134 days it amounts to ± 6·6 ; and with the period 4·058 days reaches ± 8·5. If the star be considered to have no orbital motion, the residual error is ± 7·2 miles. It appears, therefore, that the Greenwich observations of 1886 to 1889 are best represented by the period 3·970 days. Prof. Vogel then goes on to say :—

"I repeat, with the new values, the calculation of the extent of the orbit and the mass of the stars, which I gave in my first communication on this subject. Upon the supposition of a circular orbit, the resulting period is 4·0134 days, while the two components have equal masses and a velocity of 12·3 miles per second. The mass of the system is 2·6 that of the sun, and the distance of each component from the common centre of gravity is 679,000 geographical miles. With a parallax of 0″·2 the maximum apparent distance amounts to 0″·014, so that the satellite cannot be seen with the strongest instrument.

"Finally, I must not omit to say that, by means of repeated examinations of the photographic plates and measurements of the spectrum, it appears more and more certain that the satellite of α Virginis has made itself apparent on the impressions. On several plates, taken at the time of maximum movement, one edge of the Hγ line seems to be rather more undefined and more gradually to diminish in intensity than the other edge; also on some other plates, taken at the time of minimum motion, the Hγ line seems to be rather narrower. These plates also show other lines in the spectrum more plainly on account of their being less faint. These appearances go to show that the satellite has a similar spectrum to the primary star, and that the Hγ line is also broad and faint, but so faint in comparison to the line in the spectrum of the primary star that its presence is only suspected after most careful examinations of the photographs. The phenomenon observed has no influence on the measurements. If, however, the spectrum of the satellite were stronger, it might exercise an influence on the measurements of the maximum motion by causing the differences to measure somewhat less than they really are.

"The satellite, if we grant that it really exists, is probably of about the third magnitude, and it may be possible that powerful reflectors may demonstrate its presence by showing more distinctly the slight periodic changes in the composite spectrum."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 11, 1890.—"Photometric Observations of the Sun and Sky." By William Brennand. Communicated by C. B. Clarke, F.R.S.

The paper begins with a short account of the various papers communicated by Sir H. Roscoe, and published in the Transactions of the Royal Society.

My observations were made at Dacca, East Bengal, in 1861–66, repeated at Milverton, in Somersetshire, during the last two years. My first experiments were directed to ascertaining the action of the sun on sensitized paper exposed at right angles to the solar rays for different altitudes of the sun, and largely to ascertaining the laws of distribution of the actinic power in the sky.

I take no observations except when the sky is quite clear.

The method of measurement I adopted is the darkening produced in sensitized paper. I cut strips from one uniform sheet of ordinary photographic paper. My observations being relative, I obtain the same results (ratios) with any paper. I compare ultimately the effects of the sun and of a candle on this same paper.

I assume that, in burning a stearine candle, the chemical action is proportional to the material consumed; I have taken as my unit (i) of measure of chemical action the darkening produced at a distance of 1 inch from the wick of the candle when 100 grains were consumed, which in the candle I used in India occupied about forty-seven minutes. My observations, being almost entirely relative, are independent of these assumptions, which affect hardly any of my results except comparisons with the absolute unit measures of Sir H. Roscoe.

The water-motion actinometer, with which observations of the action of sun and sky were made, is the instrument depicted in the photograph (see figure).

[The water-motion actinometer was shown and explained. By it, a shutter is removed with uniform velocity from a strip of sensitized paper, which is thus, by any light to which it is exposed, tinged with a gradually intenser depth from 0 to 16 seconds (the paper being suddenly covered at the end of 16 seconds). If, for example, at a particular altitude of the sun, the action of the sky alone in 6 seconds produced the same depth of tint that the action of the sun alone produced in 10 seconds (in a similar strip cut from the same paper), then I estimate the chemical effect of the sun to have been $\frac{6}{10}$ that of the sky, *i.e.* it would be 0·6 if the effect of the sky was taken as the unit of measurement. In the same unit, the effect of the sun and sky together would be 1·6; that is, it would require $3\frac{3}{4}$ seconds' exposure to sun and sky together to produce the unit tint of measurement in the same paper, which calculated value could be immediately verified by another strip cut from the same paper. I have repeatedly made such verifications, which give me a test of the degree of accuracy with which tints can be matched.

By comparing a strip thus gradually shaded in proportion to the time, with another strip shaded as the inverse square of the distance from a near source of light, it is readily shown that the effect of a light acting at the distance unity for four seconds is equal to that of the same light acting at the distance $\frac{1}{2}$ for one second.

Observations of these ratios can be made with any *uniform* piece of paper from which the strips are cut. In the early experiments at Dacca I prepared sheets of sensitized paper with great care. I have found, in later experiments at Dacca and in Somersetshire, that any sheet of fairly good photographic paper gives satisfactory results; *i.e.* the error introduced by

Water-motion actinometer.

want of uniformity in one sheet of paper is inappreciable in comparison with the margin of possible error in the "reading," *i.e.* the matching of tints.

I originally took as my unit of absolute measurement a particular tint produced in a piece of particular paper by a Dacca candle. I found that at an altitude α of the sun this tint was produced (by the effect of the sun alone) in the same paper in (say) 16 seconds, *i.e.* the effect of the sun alone at altitude α was represented by the number $\frac{1}{16} = 0·0625$. By the system of ratios, I found the corresponding numbers for all altitudes 10° to 45°. These ratios were the means of very numerous observations extending over several cold seasons at Dacca where I had a perfect sky for months. If at any time I wish to recover the Dacca unit of measurement *in any particular paper*, I take a sun strip (at any altitude of the sun, γ) in the water-motion actinometer; I see in my table (B) that for the altitude γ the effect of the sun alone is (say) 0·12; I make a mark on my sun strip at the point where it has been exposed $8\frac{1}{3}$ seconds; the effect at that point in that paper is my Dacca unit.

My English observations have been taken in this manner without any reference to a candle. The observations of Sir H

Roscoe, apart from my own very numerous observations, show the chemical effect of the sun to be always the same (in a perfectly clear sky) at the same altitude.]

For obtaining the effects of the sun and sky, I have always experimented mainly by exposing the paper at right angles to the sun's rays. Sir H. Roscoe, on the other hand, exposes his paper on a horizontal plane. Theoretic considerations have led me to another method of observation (with the "octant" actinometer below) which gives directly the measure of the effect really desired.

A table is given of the first observations I made, which afterwards led to the formation of Table B.

TABLE B.—*Chemical Action of the Sun and Sky.*

Sun's altitude.	Sun alone.	Sky alone.	Sun and sky together.	Sun's altitude.	Sun alone.	Sky alone.	Sun and sky together.

N.B.—For sun altitudes 50° to 90°, the figures are not the result of direct observations; for sun altitudes 1° to 10°, the figures are less certain by reason of thin haze often present.

The numbers of the table were obtained, by taking the inverse of the times required at each altitude for producing the darkening of the candle unit.

I found the chemical action of the sun, as far as my experiments went, the same at all hours of the day and at all seasons of the year. And in Somersetshire I got exactly the same chemical action of the sun as at Dacca. Observations near the horizon cannot be depended upon.

Various observations had led me to suspect that the chemical action of the sky at the same moment was different in different parts of it. To investigate this suspicion, I designed an instrument which I call the mitrailleuse actinometer. I mount a number of similar cylindrical tubes in one plane in a semicircle, to the centre of which the axis of each tube is directed: one extremity of each tube lies in the circumference of the circle; the other extremities lie on a concentric circle of about one-half the radius. In the circumference of this smaller circle is a semicircular series of holes, against which a semicircular block carrying the sensitized paper is pressed by a screw. Each cylinder cuts out of the sky a circle of 8° 28′ angular diameter. One of the tubes near its top carries a small plate of wood on which stands a stile parallel to the tube, by means of which this particular tube can be brought in a line with the sun. By another motion the plane of the tubes can be adjusted to the plane of symmetry (or elsewhere).

[A vertical plane through the sun at any time divides the visible sky into two exactly similar portions. I call this the plane of symmetry.]

The observations (Table C) were taken December 23, 1864, at Dacca (among other similar observations taken in the same cold weather) in the plane of symmetry. The barrels of the mitrailleuse were fixed 10° apart, the altitude of the sun being 42° 28′.

I give the table as an early observation that shows well that there is a point of minimum sky intensity at 90° from the sun. It also appears that if i_α be the intensity for the altitude α of the sun (= 0·12), then the intensity of the sky at a point $\theta°$ from the sun is given (roughly only according to this table) by the formula

$$i_\alpha \operatorname{cosec} \theta.$$

This observation was made in the plane of symmetry: it turns out that the value, $i_\alpha \operatorname{cosec} \theta$, gives the intensity very accurately, for any point, in any other *great* circle, whose distance from the sun is $\theta°$ measured on that circle.

For any altitude of the sun (α), the chemical action of the sky is a minimum at all points in a great circle the plane of which is at right angles to the line joining its centre to the sun.

[This plane I call the plane of minimum intensity (i_α).]

As the whole of the mathematical developments of this paper are founded upon the law that at any point of the sky whose distance is $\theta°$ from the sun

$$\text{the intensity} = i_\alpha \operatorname{cosec} \theta,$$

I have been careful to verify it by numerous observations both at Dacca and in Somersetshire, and also to vary the observations in every way I could devise. Thus the mitrailleuse has been placed in the plane of minimum intensity. In this case all the barrels give the same reading for points not too near the horizon.

Next the mitrailleuse was placed in planes of great circles through the sun at various angles with the plane of symmetry; by turning it round the line joining one of its tubes with the sun the observed chemical actions agree well with

$$i_\alpha \operatorname{cosec} \theta.$$

Next by means of stops I made the aperture of each barrel of the mitrailleuse to be

$$c \sin \theta,$$

where $\theta°$ is the distance of the axis of the barrel from the sun; this mitrailleuse being exposed, the barrel $c \sin 0$ being directed to the sun, the circular darkened spots were found to be very accurately of the same depth.

Further, I calculated the *times* of exposure for a (particular) mitrailleuse with barrels of uniform aperture, which ought, on the law $i_\alpha \operatorname{cosec} \theta$, to give a uniform tint. I exposed this mitrailleuse for these calculated times, first in the plane of symmetry, afterwards in a plane inclined to it at 62°; the results agreed closely with my anticipation, and show $i_\alpha \operatorname{cosec} \theta$ to be a very good approximation.

I have therefore made full use of the expression $i_\alpha \operatorname{cosec} \theta$ for the chemical action of the light of the sky in a circle θ from the sun (whose altitude is α).

I calculate (having given me i_α, the chemical action in the circle of minimum intensity) the total chemical action of the sky, first, on a plane exposed at right angles to the sun; second, on the horizontal plane. The first is an elliptic integral, the second is $2i_\alpha(\pi \sin \alpha + 2 \cos \alpha)$. By these values I am able to compare some of Sir H. Roscoe's observed values with my own.

The mathematical processes in reducing these integrals suggested to me (within the last few months) the construction of the octant actinometer, a new instrument which I tried in Somersetshire in October last. I am fairly satisfied with the results considering the imperfect sky of England. This instrument measures the value i_α directly; and it possesses, moreover, the great advantage of not taking in the low band of sky near the horizon, and thus avoids a principal element of uncertainty in other observations.

Geological Society, December 17, 1890.—Mr. W. H. Hudleston, F.R.S., Vice-President, in the chair.—The following communications were read:—On nepheline rocks in Brazil: ii. the Tingua mass, by Mr. O. A. Derby. In a former paper the general distribution of the nepheline rocks, so far as known, was given, with a particular description of a single one, the Serra de Pocos de Caldas. The present paper treats of a second mass, the Serra de Tingua, a high peak of the Serra do Mar, some forty miles from Rio de Janeiro. This peak is essentially a mass of foyaite rising to an elevation of 1600 metres, on the crest and close to the extremity of a narrow gneiss ridge of a very uniform elevation of about 800 metres. As seen from a distance, the conical outline and a crater-like valley on one side are very suggestive of volcanic topography. In the structure of the mass both massive and fragmental eruptives are found, the former greatly predominating. The predominant rock is a coarse-grained foyaite which is found everywhere in loose blocks about the margins of the mass, but not extending beyond it. In the numerous cuttings in the immediate vicinity, dykes of phonolite and basic eruptives (augitite) are exceedingly abundant, foyaite never appearing in a dyke form. There is, however, abundant evidence that foyaite and phonolite are but different phases of the same magma. Aside from the dyke phonolites, true effusive phonolites associated with fragmental eruptives (tuffa) were found high up in the crater-like valley, proving that the mass was a volcanic centre in the most restricted sense of the word. This conclusion affords an explanation of some of the peculiarities of the foyaite, which has many characteristics of effusive eruptives mingled with those of the deep-seated ones (*Teifengesteine*). These have, aside from the porphyritic structure, a *schlieren* structure revealed by a peculiar fluted weathering (illustrated by a photograph) and the presence of pseudo-crystals in the form of leucite. Stratigraphically the Tingua foyaites lie in sheet-like masses like lava-flows, extending from the higher to the lower portions of the mountain, the underlying gneiss being revealed at nearly all levels, wherever the mass has been scored by streams. The general fragmentary character of the rock seems to be due to the undermining of these sheets. Specimens and photographs illustrating the peculiar pseudo-crystals in the form of leucite that occur in both the foyaites and phonolites of Tingua (although no leucite has been detected in the rock) were exhibited and discussed. After the reading of this paper there was a discussion, in which the Chairman, Mr. Bauerman, Mr. Hulke, Prof. Green, and the author took part.—The variolitic diabase of the Fichtelgebirge, by Mr. J. Walter Gregory.

EDINBURGH.

Royal Society, December 15, 1890.—Prof. Crum Brown in the chair.—Prof. Tait communicated a paper, by Dr. E. Sang, on the extension of Brouncker's method to the comparison of several magnitudes. The method employed is essentially an application of continued fractions.—Prof. Tait also communicated a paper by Mr. A. M'Aulay, on proposed extensions of quaternion powers of differentiation. In this paper, Mr. M'Aulay discusses a proposed modification of quaternion notation which leads directly to remarkable extensions in the mathematical treatment of the theories of elasticity and of electricity. His object in communicating this paper to the Society is to obtain information as to the likelihood of his modified notation—which is entirely opposed to ordinary conventions—being accepted by scientific men.—Prof. Ewing exhibited a model illustrating a molecular theory of magnetism. The model consists of a number of pivoted magnets which are arranged in parallel rows. These magnets are placed in the interior of a rectangular coil of copper wire, around which an electric current can be made to pass. So long as no current passes around the wire, the magnets arrange themselves in positions of stable equilibrium under their mutual forces, some of them pointing in one direction, some in another. This illustrates the condition of non-magnetized steel. If a feeble current be now passed round the coil, each magnet is slightly turned from its first position, which, however, it reassumes when the current is stopped. This illustrates the first stage of the process of magnetization. A somewhat stronger current causes instability among the originally less stable groups of the magnets, so that the magnets composing these groups swing round into a new stable position. As the strength of the current increases still further, more and more groups break up, until all have taken the new position of equilibrium under their own mutual forces and the external directive force. This illustrates the second stage of magnetization, in which the ratio of magnetization to magnetizing force increases with great rapidity. The third stage, in which the above ratio is practically constant, is exemplified by the fact that an infinite force is now needed to make the magnets point exactly in the direction of the external lines of force. If the current be now stopped, a considerable proportion of the magnets retain their final position of equilibrium —in other words, magnetic retentiveness is exhibited. The model may be made to exhibit the effects of strain on the magnetic properties. For this purpose the magnets are placed on a sheet of india-rubber. If the india-rubber is stretched, the magnets are separated out from each other in one direction, and are brought nearer to each other in a direction at right angles to the former. The magnetic susceptibility is increased, or diminished, according as the stability of the magnets is diminished, or increased, by the alteration of relative position. Similarly, the increase of the susceptibility of iron with rise of temperature is explained by the diminution of mutual magnetic influence which results from increased distance. Prof. Ewing suggests that the total loss of magnetization which occurs at a high temperature is due to continuous whirling motion of the magnetic molecules. The dissipation of energy which occurs when hysteresis is exhibited is due to the induced currents which are caused by angular motions of the magnets.—Dr. Gulland read a paper on the development of adenoid tissue. He believes that ingrowth of the epithelium (for example, in the development of the tonsils) compresses the connective tissue, and renders difficult the passage of leucocysts. The leucocysts consequently increase in numbers at the part, and eat their way through the condensed tissue.

SYDNEY.

Royal Society of New South Wales, October 1, 1890.—Dr. Leibius, President, in the chair.—A discussion took place upon the paper read at the September meeting by Prof. Warren, on some applications of the results of testing Australian timbers to the design and construction of timber structures.

November 5.—Dr. Leibius, President, in the chair.—The following papers were read:—Geological notes on the Barrier Ranges silver-field, by C. W. Marsh.—Record of hitherto undescribed plants from Arnheim's Land, by Baron Ferd. von Mueller, K.C.M.G., F.R.S.—Some folk songs and myths from Samoa, translated by Rev. T. Powell and Rev. G. Pratt, with an introduction and notes by Dr. John Fraser.—Mr. H. C. Russell, C.M.G., F.R.S., exhibited and described some of the surprising star photographs recently taken at Sydney Observatory.

PARIS.

Academy of Sciences, December 29, 1890.—M. Hermite in the chair.—List of prizes awarded to successful competitors in 1890:—*Geometry*: Grand Prix des Sciences Mathématiques, M. Paul Painlevé; honourable mention, M. Léon Autonne; Prix Bordin (not awarded); Prix Francœur, M. Maximilien Marie; Prix Poncelet, M. le général Ibañez. *Mechanics*: Extraordinary Prize of 6000 francs—this has been divided between M. Madamet, MM. Ledieu and Cadiat, and M. Louis Favé; Prix Montyon, M. le colonel Locher; Prix Plumey, M. Jules-Ernest Boulogne. *Astronomy*: Prix Lalande, M. J. V. Schiaparelli; Prix Damoiseau (not awarded); Prix Valz, Prof. S. de Glasenapp; Prix Janssen, Prof. C. A. Young. *Statistics*: Prix Montyon, Dr. Paul Topinard; honourable mention, M. Dislère. *Chemistry*: Prix Jecker, divided between the late M. Isambert and M. Maurice Hanriot. *Geology*: Prix Vaillant, M. Marcel Bertrand; Prix Fontannes, M. Ch. Depéret. *Physical Geography*: Prix Gay, M. Franz Schrader. *Botany*: Prix Desmazières, M. Maurice Gomont; Prix Montagne, divided between M. Paul Hariot and Dr. Albert Billet. *Anatomy and Zoology*: Prix Bordin (not awarded); Prix Savigny, divided between Dr. Jousseaume and M. R. P. Camboué; Prix Thore (not awarded); Prix Serres, M. Camille Dareste. *Medicine and Surgery*: Prix Montyon, divided between M. Félix Guyon, M. Auguste Ollivier and M. Paul Richer; mentions were accorded to M. Ch. Fiessinger, MM. J. Chauvel and H. Nimier, and M. Ch. Mauriac; Prix Bréant, divided between M. G. Colin and M. A. Layet; Prix Godard, M. Samuel Pozzi; honourable mention, MM. Ch. Monod and O. Terrillon; Prix Barbier, M. Claude Martin; honourable mention, M. Gaston

Lyon and M. B. Dupuy; Prix Lallemand, divided between Mme. Déjerine-Klumpke and M. G. Guinon; Prix Dusgate (not awarded); Prix Bellion (not awarded); Prix Mège, M. Nicaise. *Physiology:* Prix Montyon, divided equally between M. E. Gley and M. E. Wertheimer; honourable mention, M. E. A. Alix and MM. G. Arthaud and L. Butte; Prix Pourat (not awarded). *General Prizes:* Prix Montyon (Unhealthy Industries), M. Casimir Tollet; Prix Jérome Ponti, M. R. P. Colin; Prix Trémont, M. Beau de Rochas; Prix Gegner, M. Paul Serret; Prix Delalande-Guérineau, Dr. Verneau; Prix de la fondation Leconte, M. Prosper de Lafitte; Prix Laplace, M. Bailly.—The following prizes were proposed for the year 1891:—Prix Francœur: For discoveries or useful works tending to further the progress of pure and applied mathematics. Prix Poncelet: For the author of any work tending most to further the progress of pure and applied mathematics. Extraordinary Prize of 6000 francs: Any improvements tending to increase the efficiency of the French naval forces. Prix Montyon: Mechanics. Prix Plumey: Improvement of steam-engines or any other invention contributing most to the progress of steam navigation. Prix Dalmont: For the engineer who shall present to the Academy the best work on bridges or on highways. Prix Fourneyron: Improvements in the theory of steam-engines which take most account of the exchanges of heat between the water and the cylinders and tubes. Prix Lalande: Astronomy. Prix Damoiseau: Improvements of the lunar theory which consider inequalities of long period caused by planets. Prix Valz: Astronomy. Prix Janssen: Astronomical physics. Prix Montyon: Statistics. Prix L. La Caze: The best work on physics, chemistry, and physiology. Prix Jecker: Inorganic chemistry. Prix Delesse: The author of the best work on geological science, or, in default of such, mineralogical science. Prix Bordin: The study of the phenomena of the fecundation of Phanerogamic plants, with particular reference to the division and transport of the cellular nucleus; also the study of the connections which exist between these phenomena and those observed in the animal kingdom. Prix Bordin: Comparative study of the auditory nerves of warm-blooded Vertebrata; Mammiferæ and Birds. Prix Desmazières: The best work on the whole or any part of Cryptogamic flora. Prix Montagne: The author of important works on the anatomy, physiology, development, or description of the lower Cryptogamic plants. Prix Thore: Works on the cellular Cryptogams of Europe, and on the habits or anatomy of any species of European insect, alternately. Grand Prix des Sciences Physiques: On the organs of sense of Invertebrata, from an anatomical and physiological point of view. The prize may be awarded for a complete work on one of the organs of sense in a group of Invertebrata. Prix Savigny: For young zoological travellers. Prix da Gama Machado: On the coloured parts of the tegumentary system of animals, or on the genital matter of living beings. Prix Montyon: Medicine and surgery. Prix Bréant: The discovery of a cure for Asiatic cholera. Prix Godard: On the anatomy, physiology, and pathology of genito-urinary organs. Prix Chaussier: Important works in legal or practical medicine. Prix Barbier: The most important discovery in surgery, medicine, pharmacy, and botany, having reference to the healing art. Prix Lallemand: Researches on the nervous system in the widest sense of the term. Prix Bellion: Works or discoveries serviceable to the health or to the improvement of the human species. Prix Mège: The author of a continuation and completion of Dr. Mège's essay on the causes that have retarded or favoured the advancement of medicine. Prix Montyon: Experimental physiology. Prix Pourat: Functions of thyroid bodies. Prix Martin-Damourette: Therapeutic physiology. Prix Gay: Newly formed lakes and how they become stocked. Prix Montyon: Unhealthy industries. Prix Cuvier: The most remarkable work on the animal creation, or on geology. Prix Trémont: For any naturalist, artist, or mechanic, needing help for carrying out any project useful and glorious for France. Prix Gegner: In aid of any man of science distinguished for his works towards the advancement of the positive sciences. Prix Jean Reynaud: For the most meritorious work produced in a period of five years. Prix Petit D'Ormoy: Pure and applied mathematics, or applied and natural science. Prix Laplace: For the best student leaving the École Polytechnique.

BRUSSELS.

Academy of Sciences, November 8.—M. Stas in the chair.—On the variations in latitude observed at Berlin, Potsdam, and Prague, by M. F. Folie. The periodical changes in the declination of stars, due to aberration, is adduced as a possible cause of latitude variation.—On the Belgium graptolites, by Prof. C. Malaise.—On the points of variation in cubes, by M. Cl. Servais.—On dypnone, $\begin{matrix} C_6H_5 \\ CH_3 \end{matrix}\!\!>\!C = CH . CO . C_6H_5$, by M. Maurice Delacre.—On the new species *Posadæa*, belonging to the family of Cucurbitaceæ, by M. Alfred Cogniaux.—The reduction of nitrates to nitrites by seeds and tubercles, by M. Émile Laurent. The author makes known the results of his new researches on the reduction of nitrates. He has experimented on Indian corn, barley, peas, white lupines, broad beans and kidney beans, previously sterilized, but afterwards allowed to germinate. The crops obtained are immersed in a 1 per cent. solution of potassium nitrate, and give rise to the production of potassium nitrite. With regard to this action it is concluded that "La réduction des nitrates en nitrites par les végétaux est, comme la fermentation alcoolique, une conséquence de la vie qui se continue dans un milieu privé d'oxygène libre." This reduction of nitrates by the tubercles of the Jerusalem artichoke, radish, turnip, &c., by their petioles, and by the peduncles and fruits of different plants, has also been observed.

STOCKHOLM.

Royal Academy of Sciences, December 10, 1890.—The third and fourth part of "Erythrææ exsiccatæ" exhibited and commented on by Prof. Wittrock.—On the genera Kurutas, Nidularium, and Regelia, of the family of the Bromeliaceæ, by Dr. C. Lindman.—Researches on the structure of the central nervous system of the Evertebrates and especially of the Crustacea, and in general on the connection between the nervous cells and nervous filaments in the nervous central organs, by Prof. G. Retzius.—Contributions to the question of secular perturbations, by Dr. K. Bohlin.—The influence of the temperature on the capillary constants of some fluids, by Herr Tinnberg.—On the reaction of the iodohydric acid on 1–6 nitro-naphthalin-sulphon-acid-amid, by Herr A. Ekbom.—"Sur la notion de l'énergie libre," by Herr A. Rosén.

CONTENTS. PAGE

THURSDAY, JANUARY 15, 1891.

THE INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

INTERNATIONAL Congresses on Hygiene have been held at about two years' interval in various capitals of Europe since the year 1877. The first was held at Brussels under the especial auspices of the King of the Belgians, and was accompanied by an Exhibition of Sanitary Appliances. After the second of these Congresses, it was decided to associate with the Hygienic Congress one on the cognate subject of demography, which may be defined as the science of statistics applied to the social well-being of the people. The Congress which will assemble in London in August next will be the seventh on hygiene, and the fifth on demography. The last Congress was held at Vienna under the auspices of the Crown Prince Rudolf in 1887. It was then settled that the next Congress was to be held in London, and the year 1891 was selected; because the organizers of the French Exhibition had already announced Congresses on cognate subjects to be held in 1889 in Paris.

The object of these Congresses is to promote the interchange of views between those persons in various countries who have studied the subjects of hygiene and demography, especially with respect to their bearing upon the welfare of the people, as well as upon the intercourse between nations. So far as regards hygiene, in these days of rapid transit, the sanitary condition of any one nation is more than ever a matter of concern to its neighbours, and assemblies of delegates of different nationalities for the discussion of hygienic problems, and the comparison of hygienic methods, are of great importance. For instance, among the most prominent of the subjects which have been treated at these Congresses, has been that of quarantine. England has for some time maintained the view that the efficient sanitation of a country, and especially of seaport towns, is a better safeguard against the importation of cholera than any measures of quarantine. No doubt England has been somewhat at a disadvantage in maintaining its argument, because, whilst it has attended carefully to the sanitation of this country, it has allowed the sanitation of India, which is the birthplace of cholera, to remain in a disgraceful condition. Yet for all that, whilst at the earlier Congresses the views of England upon this important question were entirely set aside, at the last Congress the discussions which had arisen at previous Congresses had so permeated the minds of students of hygiene on the Continent, that it was generally conceded at the Vienna Congress that the enforcement of the laws of health amongst the population of a country was a far more effective measure for preventing the spread of cholera in the country than any measures of quarantine. We may therefore hope that the discussions which will take place at the Congress in London will still further awaken Continental nations to the advantages of sanitation in contradistinction to the absurdities of quarantine; and will also be a means of compelling our Indian authorities to bestir themselves to remove the stigma which now attaches to India of affording a prominent instance of defective sanitation.

In addition to this, numerous social questions intermixed with hygiene now press for a solution, which can be arrived at only after discussion. The term demography is new in this country. Dr. Mouat, the eminent President of the Statistical Society, has, in his late very able address to the Society, given an interesting explanation of the origin of the term. The following extract may advantageously be given here:—

"The term 'demography' is not to be found in any of our dictionaries, even of tolerably recent date, and in France is only contained in the great work of Littré, who denominates it 'a didactic expression descriptive of peoples as regards the population in relation to ages, professions, dwellings, &c.,' and he also adopts the definition of Quetelet, that it is 'the natural history of society.' The appellation appears to have been first employed by M. Galliard in his 'Elements of Human Statistics, or Demography,' published in 1855. The first President of the Society, the late Dr. Bertillon, treated it as dealing with the inner life of the social bodies which form a people (births, marriages, deaths, migrations, &c.), but only in their collective influence, of which it measures the powers of the parts or of the whole, without meddling with biological proceedings, which distinguish it from physiology."

Dr. Bertillon regarded England as the real home of demography, as it surpassed all other nations in the incomparable richness of its demographic inquiries, and in the unbroken continuity of its published returns.

The subjects which will be open to discussion in the Congress may be classed under the following general heads:—(1) The prevention of communicable diseases, as, for instance, (*a*) whether sanitation or quarantine is most efficient against cholera; (*b*) how the spread of disease from milk and from water can be checked; (*c*) the relation which tuberculosis and other diseases in animals bear to mankind; (*d*) vaccination, the prevention of leprosy, rabies, and such like contagious diseases; (*e*) the effect of soil on communicable diseases; (*f*) disinfection and disinfectants. (2) The science of bacteriology in relation to communicable diseases. In connection with this subject an exhibition of microscopic and cultivation specimens would be arranged. (3) Industrial questions, as, for instance, the regulation of industrial occupations from a health point of view, including the length of hours of labour in different occupations, the influence of dwellings upon labour, and the effect of large cities on the health of the population; the influence of the health condition of the people, and the effect of different sorts of food and of wages upon the efficiency of labour. (4) The hygiene of infancy and childhood, as, for instance, protection and insurance of infant life; school hygiene, including length of hours of study, nature of studies, and the effect of physical training; school buildings and their accessories, and other educational questions bearing on health. (5) The hygiene of houses and towns, including questions of width of streets, height of buildings, air space round houses, house construction, water supply, river pollution, drainage, treatment of refuse, disposal of the dead. (6) State hygiene, or the duty of the Government towards the nation in regard to health, and the machinery necessary for exercising that duty; the duties of communities towards each other in regard to questions of health, and towards the individuals of which they are composed; the laws for notification and isolation of disease; the status and education of medical officers of health and of sanitary inspectors.

In consequence of the wide scope covered by these subjects, it is proposed that the work of the Congress shall be divided between ten Sections. The order in which they will stand is not finally settled, but they may be briefly summarized as follows:—(1) Demography, which necessarily involves questions of industrial health; (2) communicable diseases; (3) bacteriology; (4) diseases of animals in relation to man; (5) hygiene of infancy and childhood; (6) engineering in relation to hygiene; (7) architecture in relation to hygiene; (8) chemistry in relation to hygiene; (9) military and naval hygiene; and last, but not least important, (10) the functions of the State in relation to hygiene.

The Prince of Wales, who has so deep a personal interest in all matters relating to the well-being of the community, at once acceded to the request made to him to accept the post of President of the Congress; and the British Presidents and other officers of Sections will be among the most eminent men in their several departments of knowledge. Upon them will lie the duty of organizing the work of the several Sections before the Congress meets. They will be supplemented at the meeting of the Congress by foreign or colonial and Indian representatives, distinguished in the several branches of science included in the programme. It may be mentioned that above 2000 members, exclusive of representatives from Great Britain, attended the Vienna Congress; and it is anticipated that the Congress in London will attract at least an equal number of persons from foreign countries, because Great Britain affords so many examples of important sanitary works, as well as of institutions having the preservation or restoration of health as their main object.

The expenses of correspondence and other matters connected with the organization of the Congress are so large that appeal is made to those interested in the subjects to be discussed to aid the work by moderate contributions.

GEOLOGICAL TEXT-BOOKS.

Class-Book of Geology. By Archibald Geikie, F.R.S. Second Edition. (London: Macmillan and Co., 1890.)

Elementary Geology. By Charles Bird, B.A., F.G.S. (London: Longmans, Green, and Co., 1890.)

ALL who care for geology, teachers and students especially, will hail with delight the appearance of a second edition of Dr. A. Geikie's "Class-book." All the more that it may now be had at less than one-half the cost of the first edition. Such a substantial reduction in the price of a scientific book is a piece of liberality and far-seeing policy which it could be wished were more common. Too often, when a rapid sale of such a work has proved that its value is appreciated and its success assured, there seems to be a feeling that its established reputation may be relied upon to ensure a demand for it in the future equal to that of the past, and that it will be quite safe to keep up its price. But no such purely mercantile views have prevailed here, and we may feel sure that both publishers and author have been actuated first of all, in the bold step they have taken, by a wish to promote the extension of knowledge by placing within the reach of as many as possible a work so well got up, so admirably illustrated, and so full of matter presented in an eminently readable form. And there can be little doubt that this disinterested conduct will reap the reward it deserves. Many a teacher will bear me out that the book has been a universal favourite. Students who would not put up with the dry compendium of the normal text-book have been won over by its attractive style; and even those earnest workers, who despise or excuse the absence of literary elegance, have found their labours lightened and have felt an added pleasure when their first introduction to geology has been through the medium of this class-book. One thing only prevented its being adopted far and wide as a text-book in the school and lecture-room. Now that obstacle is removed, it is sure to come into more and more extensive use; and it may be confidently predicted that a rapidly increasing sale will soon recoup those concerned for y temporary loss that their generous treatment of the public may at first occasion.

It is the conviction that it will not be long before a second opportunity for revision presents itself, and a wish to give, if it can be done, some help towards making so excellent a book more perfect still, that embolden me to be critical, and to point out a few minor points which seem capable of emendation; and I take this course with the less hesitation, and with no fear of being misunderstood, because I have endeavoured, in a previous notice of the first edition, to do justice to the many excellences of the work and to explain its scope.

I cannot say that the account of the formation of "flood plains," on p. 39, quite commends itself to my mind. The author postulates the existence of an alluvial flat, over which sand and silt are deposited during floods, but he does not explain how this flat is produced. Possibly the required explanation may be found in his "Physical Geography," which he recommends should be read in connection with the present work. If this be so, a reference to the passage required would be useful: indeed, wherever the one book is required for the elucidation of the other, it might be well to call attention to the fact in a note. The impartial and judicious blending of Darwin's and Murray's views on the growth of coral reefs is much to be commended. If we take into account the vast number of cases in which minerals occur without any external crystallized shape, it seems hardly safe to say that they have "in most cases a certain geometrical form" (p. 123). But the mineralogical sketch seems capable of improvement in more than one direction. The using "sides" and "faces" as if they were convertible terms, in the description of rock-crystal on p. 124, is apt to engender confusion of thought. In the account of felspars there is no mention of their cleavages, a property so often of practical value in distinguishing them from quartz, and a property far more easily recognized by the beginner than their monoclinic and triclinic crystallization. In some cases—mica, for instance—there is no mention of hardness, where that is a character useful in identification. It would not be fair to blame a geologist for the definition of the systems of crystallization given in the book before us, as long as it still survives in treatises on mineralogy. But it is much to be desired that the number and position of certain ideal axes should not be the starting-point for classification. If the grouping were based on the degree of symmetry possessed by each system, and it were afterwards, if necessary, pointed out that ideal axes had their uses, the point of real importance would have its due place, and things of subsidiary value would find their proper level. But, really, the amount of crystallography that there is room for in an elementary treatise on geology is so small, and it is so hopeless to attempt in this space to convey any idea of what crystallography means, that the subject in its general form had better be passed over altogether; it would be quite enough to explain what is meant by crystalline cleavage, and to call attention to the shape of crystals only in those cases, such as fluor spar and calcite, where they are common and easy to recognize. Many a student, who would simply be driven wild by an attempt at a systematic teaching of crystallography, has an eye good enough to enable him to recognize dog-tooth spar when he sees it, and to form a very fair idea whether an hexagonal pyramid is dumpy enough to belong to quartz. In teaching, it is quite enough, as a rule, to let the small amount of crystallography that a geologist must know drop in incidentally as occasion requires, taking special care that each fact is illustrated by a concrete example, so that the knowledge required may come in instalments and be assimilated bit by bit.

To continue in the censorious mood. The statement that "perlitic structure is one of the accompaniments of devitrification" (p. 145) is fraught with danger. Many readers, I fear, would take the words to imply that the structure is a result of devitrification, which of course is not their meaning. Why not say, "is often found in devitrified rocks, and is useful as indicating that they were once glassy"? I take decided objection to the statement, on p. 150, that grains of sand are usually rounded; as a rule, the sand-grains of a sub-aqueous sandstone are most markedly chips, and it is only when they have been exposed to æolian wear that they become even approximately rounded. The author is wisely guarded when he treats of the origin of flint; but the doctrine of the replacement of calcium carbonate by silica has so much in its favour, that it might, without much risk and with manifest advantage, have been mentioned. That quartzite is "an indurated siliceous sand" we shall all admit: it might have been usefully added that in many cases the induration has been caused by the deposition of secondary silica between its grains. In discussing the methods by which sedimentary deposits are consolidated, no mention is made of the tangential pressure exerted during great earth movements; surely this is one of the most, if not the most efficient agent in the work.

The stratigraphical part of the book is necessarily brief, but it is all to the point, and the reader ought to carry away from it clear notions as to the main features in the life and physical geography of each geological period. It is here that the distinctive excellence of the work, which places it so far above the level of the average dismal text-book, comes out most strongly. In the place of comparative tables of strata and lists of characteristic fossils, which an examinee commits to memory and forgets, we have graphic pictures of what England, and Europe in many cases, were like, and an account of what went on during geological periods—history, in fact, and written as an historian, and not as a compiler, writes. The illustrations are excellent: the author's well-known artistic skill adds a charm to the usefulness of many; and the figures of minerals, rock structures, and fossils are such faithful pictures, that, where a teacher is quite unable to procure specimens, they will to a large extent supply the want. The book closes with an appendix giving the classification of the vegetable and animal kingdoms, in which those points which are of special importance in palæontology have been judiciously picked out and made prominent.

In the preface to Mr. Bird's "Elementary Geology," we are told that "the following lessons were given to a class of thirty boys, and were very successful in arousing an interest in geology and in sending a number of town boys on long walks into the country;" and that they had also the comparatively unimportant result of enabling the class "to pass the South Kensington examination in the elementary stage of the subject." I have the best possible reason for feeling sure that the class-teaching of the author would deserve and secure the good results which he tells us followed from it. But I have grave doubts whether a beginner, who had the book alone to rely upon, would be won over to feel any great love for its subject. This, however, is no fault of the author's. As long as the main end of study is to enable the student to pass examinations, books must be written whose chief object is to help him to this end; they must be cheap, and therefore small; so they must be thickly packed. The second chapter of the work before us is an instance of how this must be done. It consists really of a definition of nearly all the terms which are to be used in the course of the work, and the reader who commits it carefully to memory will be armed with answers to a large number of the questions that may be put to him in examinations. But I am perfectly certain that Mr. Bird never gave a lesson in class, or a series of class-lessons, which is fairly represented by this chapter. No human being could survive the tedium which must be the result of thrusting upon him at one fell swoop such a crowd of new words and new conceptions. The success which crowned Mr. Bird's labours is in itself a proof that he never taught in this fashion; enthusiasm such as he kindled is not evoked by overwhelming the learner with a flood of dry statements at the outset of his career. That is just the way to create a distaste for a subject which no amount of subsequent amplification suffices to remove. Definitions we must have, but one who can teach like Mr. Bird knows how to bring them in one by one, at intervals, as they are wanted. Why his book is so unlike what must have been the style of his teaching has been explained already, and it is only giving him his due to confess that, considering how he has been trammelled, he has executed his task well, and that the book is above the average level of its class. He will, I am sure, allow me to point out, in no unkindly spirit, portions which seem capable of improvement.

There is the same crowding in chapters iii. and iv. as in chapter ii. The descriptions of the minerals in chapter iii. might enable a reader to answer some questions often set in examinations, but in many cases they would do little towards helping a student to know the mineral when he saw it, and this after all is what the real student wants. To learn how to worry out for himself that a mineral is probably a felspar is infinitely more valuable as a bit of educational discipline than to be able to write down in an examination the chemical composition of felspars. If only a few of the commoner rock-forming minerals had been treated of, it would have been quite possible in the space available to have given descriptions of the way in which a student must go to work in order to recognize them; but then some minerals must have been omitted that are liable to be "set" in examinations.

There are in the book many little slips, not very serious, which might usefully be corrected when opportunity offers. On p. 28 it should be stated that clay is hydrated. There is hardly reason to say that quartzite has been "almost melted" (p. 42); it is certain that in many cases its hardness is due to the deposition of secondary silica. It would have been as well to give some account of the physical characters of serpentine (p. 43), and greater definiteness of statement as to the minerals by the alteration of which it has been produced. I really hardly know what grounds there are for the statement, on p. 78, that the action of glaciers has had any thing to do with the production of immense perpendicular cliffs of limestone. One would have liked to see a section somewhat nearer the actual thing in the place of our old time-honoured friend the section across the Jura on p. 98. I am not sure, but I fear, that the dissolution of actual chalk in carbonated water would go on slowly (p. 45); freshly precipitated calcium carbonate dissolves fast enough, and is safer for lecture-room experiment. It is not carbonate of iron that gives a bluish-grey tint to rocks, as stated on p. 47. In chapters vii. to xi. it would seem that we have a much closer representation of the author's actual teaching than in the earlier part of the book; there is much life and brightness about them; and, while they are full of matter, it is presented in an attractive form. It would have been well to give distinctly the two main points of difference between Conchifers and Brachiopods on p. 113. The only character mentioned is that the latter are equilateral. The Trilobite on Fig. 110 is not a Paradoxides. The section on Fig. 139 is misleading; the Permian scarp nowhere towers above the Penine ridge in the way represented. It would certainly be desirable to add a word about the Alpine Trias on p. 169. The position of the siphuncle in Goniatites is incorrectly stated on p. 181. By a curious slip the Portland Beds get the credit of Mammalian remains on p. 193. In the figure of Inoceramus, on p. 213, the cartilage-pits of the hinge are described as teeth. In the notice of the Forest Bed, on p. 226, room might be found for a word about the Arctic Freshwater Bed.

After all this fault-finding, it is a pleasure to be able to call attention to the excellent character of the illustrations: they are numerous, well chosen, and admirably executed; the figures of fossils deserve special praise. The geological map of the British Isles will be most useful. It is not crowded, and the clear transparency of the colours is such as till lately was unknown in English chromolithography. The book belongs to a class that I have no great love for, but it is distinctly good of its kind; and it will prove useful in the hands of a teacher who knows how to dilute and season the condensed food which it offers, and whose aim, like the author's, is not merely to get his students through an examination, but to educate them and imbue them with the scholar's disinterested love for learning. A. H. GREEN.

ELECTRO-METALLURGY.

The Art of Electrolytic Separation of Metals, &c. (*Theoretical and Practical*). By G. Gore, LL.D., F.R.S. *Electrician* Series. (London: The *Electrician* Publishing Co., 1890.)

A Treatise on Electro-Metallurgy. By W. G. McMillan, F.I.C., F.C.S. Griffin's Scientific Text-books. (London: Charles Griffin and Co., 1890.)

ANY metallurgical process which reduces the cost of production as compared with older processes for effecting similar results must of necessity prove of great commercial importance. This is especially the case in places where labour is dear and unskilled, and fuel and refractory materials both scarce and costly—perhaps, even, absolutely unobtainable. If, too, the new process enables a metal to be produced, as in the case of copper, which possesses superior quality to the metal produced by the older process, such a metal will command a higher market price, and the use of the new process is consequently attended with important commercial advantages.

Such an improvement over ordinary metallurgical processes has been effected in recent years by the gradual introduction of electrolytic methods. They have not, however, made the rapid progress which was at one time anticipated, and at present are practically only of importance in the metallurgy of copper. There are many reasons for this. The tendency to-day is to endeavour to increase to its maximum the daily output of existing works, provided the product already attainable is of fair quality, rather than to lay down new plant, which, although it might produce a metal of greater purity, would be severely handicapped by the slowness of the work and smallness of the output as a return for the capital invested. It is in this respect that electrolytic methods for the preparation of the ordinary commercial metals fail to give satisfactory results. It is true that in the cases of gold and silver this objection does not to so large an extent apply, but, unfortunately, other circumstances have also to be considered. The metallurgy of the precious metals is for the most part effected in the immediate neighbourhood of the mines, and these, in turn, are usually situated in out-of-the-way districts. Miners, too, and mill-men are generally but slightly acquainted with a knowledge of matters pertaining to electrolytic methods, and comparatively little attention has therefore been directed in the past to the treatment of the ores of the precious metals by such methods. There can, however, be but little doubt that in the near future this will cease to be the case, and that by the improvement of known methods, and by devising new ones, electrolytic methods will attain a degree of commercial importance which at present can hardly be foreshadowed. Any sound contribution to the literature of the subject which is likely to assist in this development of metallurgical processes thus becomes of much importance. We record, therefore, with pleasure, the appearance of a manual by Dr. Gore, devoted to electro-metallurgy proper, which is likely to prove of much use in the spread of the theoretical knowledge so requisite for industrial success. The author gives much attention to this portion of the subject, but in view of the claim "that this book is written to supply a want," it is to be regretted that fuller details are not forthcoming as to the practical working of the processes, though such information as is given is well and clearly put. The greater part of it, however, has already appeared elsewhere. In the case of copper, for instance, if the working arrangements are faulty, the mud liberated on the solution of the impure copper may be deposited again on the cathodes; the tank solution, too, may vary in density, and the working become irregular with a consequent irregularity in the character of the metal produced. Here, again, excessive rapidity, fatal to the purity of the product, is very common, the result being that in the majority of instances it is necessary to melt the deposited copper, thus introducing sources of error which it is one of the main objects of the process to avoid. The incidental collection of the gold and silver in copper submitted to such a refining process may occasionally cease to be an incident and become the main object of the process, ores of gold and silver being intentionally added in the previous smelting operations.

The difficulty of obtaining admission to works employing electrolytic refining methods, which the author himself laments, is so great, that it is with all the more regret that we have to call attention to this want of fuller details as to the more recent modifications of working adopted in this country and elsewhere. The text-book is otherwise an excellent one.

The term "electro-metallurgy" has been generally applied in the United Kingdom to all operations in which a metallic deposit is produced by means of electrolysis, however small the scale of production may be. Such a designation of the art is much too broad, and it would be better to limit the use of the term "electro-metallurgy" to those processes which are employed on a large scale for the purpose of extracting or refining metals, as distinguished, that is, from ordinary galvanoplastic methods.

This criticism applies to the "Treatise on Electro-Metallurgy," by Mr. W. G. McMillan, the greater part of which relates to galvanoplastic methods proper. Metallurgical processes, however, are also considered, though but little space is given to them; and a chapter, which might well have been a longer one, is devoted to electrolytic methods of assay.

Dr. Gore, after giving a brief historical sketch of the subject, passes to a consideration of the theory of electrolysis, which is considered at some length, useful tables being also given. The mode of establishing an electrolytic refinery, together with the plant required for this purpose, is next considered, and in addition to an account of the various types of dynamo-electric machines in use for electrolytic purposes, brief descriptions are also given of the various electro-metallurgical processes which have been from time to time proposed.

In Mr. McMillan's treatise, an historical introduction to the subject of electro-metallurgy is given, accompanied by a theoretical consideration of the question. A chapter is devoted to the "sources of current," and in a series of other chapters the art of electro-plating is described. Another chapter refers to electro-typing, and others relate to the electro-deposition of the various metals and some alloys. Electro-metallurgical processes proper are also considered, together with methods of assay, and a glossary is added of substances commonly employed in electro-metallurgy. Forty-three useful tables are given as addenda, and the printing is clear and distinct.

We can recommend both these manuals, not only to students, but also to those who are interested in the practical application of electrolytic processes.

OUR BOOK SHELF.

Leçons sur l'Électricité professées à l'Institut Électro-Technique Montefiore annexé à l'Université de Liége. Par Eric Gerard. Tome II. (Paris: Gauthier-Villars et Fils, 1890.)

THIS volume completes the work the first part of which has been already noticed in NATURE (vol. xlii. p. 219). In the first volume, the general principles of electricity and magnetism and the theory of dynamo-electric machinery were explained; the volume now before us contains a very clear and full account of the most important industrial applications of electricity. The principal subjects discussed in this volume are: methods of distribution in electric lighting; transformers, and meters; the insulation of electric light cables; electric motors, both with constant and alternating currents; the transmission of power; electric railways and tramways; descriptions of the various kinds of incandescent and arc lamps; photometry; electro-metallurgy, including the deposition of metals from solutions and fused salts; electric welding. All these subjects are clearly explained, and generally illustrated by instructive diagrams and figures; the book is well up to date, and should prove of great service to students of electric technology. The only fault we have to find with it is that it contains no references which would enable the student to consult for himself papers in which the various processes are described more fully than is possible in a text-book of moderate size. This omission, though exceedingly common in French treatises, is one which we think is greatly to be deplored: in the first place, it leaves the student at the mercy of the author, for, if he does not understand the explanations in the text-book, he does not know where to turn for another with which he might have a better fate; and secondly, we hold that the habit of consulting papers in the Transactions of learned Societies and scientific journals is a most valuable one for the student to acquire, and that it has no chance of developing unless text-books contain references to such papers. J. J. T.

Fathers of Biology. By Charles McRae, M.A., F.L.S. (London: Percival and Co., 1890.)

STUDENTS of anatomy and physiology, as the author of this little book points out, are apt to suppose that the facts with which they are now being made familiar have all been established by recent observation and experiment. There could not be a greater mistake. Biology is a science of "venerable antiquity," and the way was prepared for modern discoveries by the labours of many patient and far-seeing investigators. In the present volume Mr. McRae has sought to illustrate this by sketching the biological work of Hippocrates, Aristotle, Galen, Vesalius, and Harvey. He could not have selected five inquirers better suited for his purpose; and within the limits he has allotted to himself he has succeeded admirably in indicating the nature and value of the contribution which each of them made to biological science. He is especially happy in his treatment of the three representatives of ancient research; but the essays on Vesalius and Harvey are also clear, well-arranged, and suggestive. Mr. McRae is not content with second-hand information. He has evidently studied the original sources with care; and the result is that his method of exposition is invariably fresh and interesting. He knows, too, how to connect the results attained in former times with those at which later anatomists and physiologists have arrived. He does not, of course, claim to have exhausted the interest of his subject. But the work he has done, so far as it goes, is sound, and should be of service to many of his readers in helping them to understand the various stages in the development of the scientific conceptions with which he deals.

Through Magic Mirrors. By Arabella B. Buckley. (London: Edward Stanford, 1890.)

THIS volume is intended to form a sequel to the "Fairy-Land of Science," and is written with the clearness and brightness which make that book so attractive. The power that Miss Buckley has of interesting young people in the more popular parts of the various sciences cannot be doubted, and is well shown in the present book. A magician is supposed to teach young lads; and the author is thus enabled to bring in different parts of the sciences, and to preserve a continuity throughout.

There are ten chapters, and the following are some of the headings: "The Moon," "Life-History of Lichens and Mosses," "History of a Lava Stream," "An Hour with the Sun," "An Evening with the Stars," "Little Beings from a Miniature Ocean, &c." In the chapters with these headings the uses of the telescope, spectroscope, camera, microscope, &c., are all mentioned and well explained, and their principles clearly brought out.

The information throughout is up to date, and is taken from the best sources; and the illustrations form a most important addition to the text. The frontispiece is a reproduction of Mr. Isaac Roberts's most exquisite photograph of the great nebula of Orion, taken on February 4, 1889.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Proposed South Kensington and Paddington Subway.

ALTHOUGH there can be no question but that any facilities of access to the group of buildings on the ground of the Commissioners of the Exhibition of 1851 will be greatly to the advantage of the public, the objections to the proposed railway raised in your recent article on "Shaking the Foundations of Science" are worthy of most serious consideration, if they are not altogether fatal to the scheme. The alternative route for the line which you suggest, along Queen's Gate, would meet with equal difficulties, much greater expense, and certain opposition in several quarters. There is, however, another solution of the question free from most of the objections to both the others.

Let the existing subway be continued as originally projected as a walking road to a station at the Albert Hall; and let the tramway or railway line be brought across Kensington Gardens from Paddington to meet it there. This will have the desired effect of giving easy access to the Albert Hall and neighbourhood from the north-west of London, as well as a convenient dry covered approach from the South Kensington Station. The cost of this scheme to the promoters of the railway will be far less than if they have to enlarge the present subway so as to make it available for carriages. The convenience to the public will be nearly as great. In the proposed scheme anyone coming by the District Railway must change carriages at the South Kensington Station; and there are few who, having once alighted, would not as soon take a short walk to the Museums or the Albert Hall through the subway (as was originally designed when this was made) as mount into another carriage. It will be a totally different thing from having (as now) to emerge to the upper surface, and either take a cab or trudge along a wet, dirty, and cold road. It would, in fact, be scarcely a longer walk than is often necessitated along the platforms of some of our existing railway stations.

The walking subway, instead of opposition, may well receive the cordial support of all interested in the "foundations of science," as it will lessen the number of wheels which rattle along the streets above. The marvellous improvement that it made in the state of the streets during its brief period of usefulness, the summer of the Indian and Colonial Exhibition, was apparent to all dwellers in the neighbourhood.

W. H. FLOWER.

Natural History Museum, January 12.

WOULD it not be desirable to prepare a petition to the House of Commons, to be signed exclusively by scientific men, against the proposed South Kensington and Paddington Subway Railway? A copy might lie for signature at the rooms of each of the learned Societies. ALFRED W. BENNETT.

Chemical Action and the Conservation of Energy.

IN NATURE of December 18, 1890 (p. 165), there appears a paper by Mr. Pickering under the above heading, in which some of the errors of thermo-chemists are exposed. As, on account of the well-known experimental skill of Mr. Pickering in thermo-chemistry, there may be some risk that all the positive statements in this paper may be accepted by students as facts, it is, I think, worth pointing out that some of these statements, although given positively as if they were obvious physical laws, are, to say the least, matters of controversy, whilst others are absolutely erroneous. It would seem as though prolonged calorimetrical studies lead the experimenter to regard heat changes as the only factors to be considered in cases of chemical equilibrium, since the same erroneous view of the subject has been taken by Berthelot in his "Law of Maximum Work," by J. Thomsen in a similar "Law," and now by Mr. Pickering in this paper. He concludes:—

"As a consequence of this, it follows that, in any complex system of atoms, where two or more different arrangements are independently possible, and where the various products remain within the sphere of action, and are capable of further interaction, then those products, the formation of which is attended with the greater evolution of heat, will be formed to the exclusion of the others."

It is somewhat curious that by way of clearing the ground for his own views Mr. Pickering demolishes one of the chief arguments of the older school—namely, that an endothermic reaction may occur if it forms part of a cycle of which the final result is an evolution of heat. His illustration of the impossibility of this, by comparison with a stone rolling a short way up a hill by itself in order to have a long roll down on the opposite side, is exceedingly apt. But immediately following this is a statement which must be regarded as incorrect: "No amount of heating can make an endothermic reaction possible so long as it remains endothermic."

I have characterized two statements as erroneous; perhaps I may be allowed to mention the evidence usually accepted as proving this, premising that, since it partially depends on the second law of thermodynamics, and this in its turn depends upon experiment (see J. J. Thomson, "Application of Dynamics to Physics and Chemistry," pp. 4 and 5), no argument against it is valid which deals only with single molecules. The researches of J. W. Gibbs (Trans. Conn. Acad., iii. 108, 343), of Lord Rayleigh (Proc. Roy. Inst., vii. p. 386), of Massieu (*Journ. de Phys.*, vi. p. 216, and of Helmholtz (*Sitz. Akad. Berl.*, February 2, 1882, July 27, 1883, and *Monats. der Berl. Akad.*, May 31, 1883, p. 647; also, Physical Society, Translated Memoirs, vol. i., Part 1), prove conclusively the general principle that the evolution of heat alone is not conclusive as to the possibility of a chemical change taking place in a given direction. The magnitude which does condition this change having been arrived at by different methods, in some cases independently, has received different names; thus it is the "free energy" of Helmholtz, the "characteristic function" of Massieu, the "force function for constant temperature" of Gibbs, and the "thermodynamic potential" of Duhem. All these names represent the same function, F (or − F), the integral energy (U) less the product of the absolute temperature (T) into the entropy (S); or in symbols the free energy $F = U - TS$. In the above-mentioned researches it is shown that a system will be in stable equilibrium if the free energy is a minimum. Hence, to restate Mr. Pickering's conclusion, it follows that, in any complex system of atoms or molecules, where two or more arrangements are independently possible, then the final arrangement will be such that its formation is attended with the greatest loss of "free energy." Although this work has now been published nearly fifteen years, so far as I am aware no serious attempt has been made to prove it to be inaccurate.

Let the energy, entropy, and temperature before the reaction be U, S, and T; after the equilibrium is established, U′, S′, and T′, then $(F - F') = (U - U') - (TS - T'S')$. But $(F - F')$ must be positive, *i.e.* $(F - F') > 0$. If the temperature be so low that the second term is small compared to the first, then there will be a loss of energy—an evolution of heat. But this is not the only possible case: the reaction may take place with an absorption of heat if $T'S' > TS$, and also $(TS - T'S') > (F - F')$. Here $(U - U')$ is essentially negative; in other words, the reaction will take place of itself and with absorption of heat. This will account for many apparent anomalies in high temperature reactions.

Further, as regards the statement that "no amount of heating can make an endothermic reaction possible so long as it remains endothermic," we see from the equation $F = U - TS$ that the importance of the second term increases with the temperature, and thus F may decrease by the increase in TS as well as by the more generally recognized decrease in U. U may, in fact, increase in the course of the reaction, provided that the corresponding increase in TS is larger.

Exception might also be taken to the definition given of chemical affinity as "the potential energy possessed by atoms." It is rather difficult to imagine potential energy becoming "satisfied" when the atoms combine together. As, however, there are now several works giving a complete account of the other views on this subject, it is unnecessary to discuss this point.

In conclusion, it may be as well to point out that the above remarks contain nothing new, having been known for years; but as they have not yet found their way into the text-books of thermal chemistry, and are apparently ignored by our leading thermo-chemists, it seems worth while to bring them to the notice of students. GEORGE N. HUNTLY.

Richmond, Surrey, December 22, 1890.

Forestry in North America.

THE timber-cutters, graziers, and settlers, who are rapidly destroying the forests of North America have recently obtained a valuable ally in Major J. W. Powell, Director of the United States Geological Survey; who, in his enthusiasm for the construction of dams, appears to care little from whence his countrymen are to get their future supplies of timber, whilst his proposed means for securing to them a perpetual water-supply for irrigating the farm lands below the Rocky Mountains, when confronted with the experience acquired in Europe, are likely to prove worse than useless. Most students of physical geography consider hill forests as efficient aids in storing water, but not so Major Powell; for in the April number of the *Century Magazine* in a paper on the "Non-irrigable Lands of the West," and in another paper published in the August number of the *North American Review*, entitled "The Lesson of Conemaugh," he advocates the denudation of the higher slopes of the Rocky Mountains, in order to allow snow-drifts to accumulate in the folds of the hills, and afford a perennial supply of water for irrigating the drier lands below the forest belt. Major Powell contends that, as long as the higher hill slopes remain forest-clad, the snow falling on them will always be uniformly distributed, and cannot be drifted together by the wind. It therefore melts away gradually, without affording a steady supply of water to the hill streams. He also asserts that in California the hill streams have increased wherever the hills have been denuded; and expresses his opinion that, although forests may be useful in districts with a heavy rainfall, as they evaporate excessive moisture rapidly from the soil, yet in drier regions this rapid evaporation is prejudicial, and therefore forests should be cleared in order to preserve the requisite amount of moisture in the soil. This appears to be a complete inversion of what actually occurs, as I hope to show further on.

Major Powell gives a most striking picture of the ease with which forest denudation may be effected in the dry coniferous forests of the Rocky Mountains. When camping out twenty years ago in this magnificent forest tract, where the growth was then so dense that not a blade of grass was to be found under the trees, but the soil was completely covered with dead needles; the Major allowed his camp fire to ignite a splendid pine tree, and watched the "welcome flame" rising till the whole tree was in a blaze. The fire soon spread to the surrounding forests, and before nightfall the country for miles around was in flames, more timber being destroyed in a few days than "has been used by the people of Colorado for the last ten years."

Major Powell, however, as we have stated, would preserve forests in the damper regions, and admitting the danger of forest fires to their existence, he proposes as a remedy a great extension of sheep-farming; so that the undergrowth of the forests may be nibbled off, and thus a great source of danger from fire may be removed. What the sheep are to find to nibble in forests where the soil is covered with dead needles, it is not easy to say; and if all undergrowth be bitten off by the sheep, the future re-growth of the forest could evidently not be assured by natural seedlings, but the older portions must be gradually fenced and planted up: if this be done on a large scale it is to be feared that even the vast resources of the States would prove inadequate. An answer has, however, already appeared in an American periodical, *Alta California*, to the Major's suggestions regretting the progress of forest arson, and anticipating that thousands of acres of the noblest timber in the world will be destroyed before the first rains next autumn. The writer states that these forest fires are chiefly due to shepherds, who burn the pine needles, and consequently the entire forest, in order to get young grass to spring up for their flocks.

So much for the real results of extending sheep-runs to preserve the forest from fire, which reminds one of a suggestion in Prof. Wallace's "Indian Agriculture"; except that this author goes further than Major Powell, and wishes to induce the Government of India to put an end to the efforts of the Indian Forest Department to protect their forests from fire, considering that Indian forest trees have grown up under a *régime* of annual fires till they have become quite inured to them, and would suffer if the fires were stopped. The Professor also urges that the Indian flocks and herds would miss the fresh young grass always springing up in burned forest, but if admitted to graze in the annually burned area, would keep down the undergrowth, the occasional burning of which in a forest protected from fire, according to him, does more damage than annual fires in well-grazed forests. It is to be feared that both the Edinburgh Professor of Agriculture and the Director of the United States Geological Survey have more sympathy for the shepherds than for the forests.

Besides the paper controverting the Major's advocacy of sheep as friends to the forest, I was glad to see two very sensible articles, in *Garden and Forest* of June 18 and September 4, entirely opposed to his theories, whilst Mr. Abbot Kenney has written a paper in the August number of the *Century* showing that the statement about the increase in volume of the hill streams in California being due to forest denudation, is at variance with the facts of the case.

There can be no doubt that directors of geological surveys should study the action of the forest as a great natural factor influencing soil and climate. In Germany, the elements of forestry are taught in primary schools as a necessary part of the general education of the country people; but the German peasants have owned forests, and participated in their benefits, for centuries, and a forest fire in France or Germany is considered a great calamity by the whole country-side: the Anglo-Saxon race on the contrary has been chiefly engaged during the last 300 years in clearing away the virgin forests of the new worlds in the western and southern hemispheres; and, as we see, the benefits of forests are still questioned by certain influential people both here and in America.

Darwin and A. R. Wallace admit over and over again the inestimable value of the forest as Nature's great conservative force; and in America, Major Powell's heresies were long ago disposed of in Marsh's "Man and Nature." In Wallace'

"Tropical Nature," we read as follows:—"A systematic planting of all hill-tops, elevated ridges, and higher slopes, would probably cure the bad effects of the intermittent rainfall of Central India; whilst the action of forests in checking evaporation from the soil, and in causing perennial springs to flow which may be collected in reservoirs, would serve to fertilize a great extent of country."

Major Powell evidently disagrees with the results of Wallace's observations, but the facts are quite opposed to his theories. Forests do not evaporate moisture nearly so fast as bare ground; and although denuded hill-sides may favour the accumulation of snow-drifts, yet they allow the rainfall to drain off rapidly, and cause dangerous floods; loosening of the soil on hill-sides; avalanches; silting up of river-beds; and frequently give rise to the complete devastation of cultivable lands at the foot of the hills, as the material washed down from above is spread over them by the floods in the form of silt, gravel, and boulders.

In Dr. Schlich's "Manual of Forestry," at pp. 43 *et seq.*, we read that experience in Germany shows evaporation from forests to be only two-fifths of that in the open country, and that the balance of water retained in forest soil increases rapidly with the altitude, so that evaporation in mountain forests may be reduced to about 10 per cent. of the rainfall. We also know that, in France and Germany, mountain forests have long been looked upon as preservers of moisture and feeders of springs. In 1889, the French Government spent 3,192,800 francs in *reboisement* works in the Alps, Pyrenees, and Auvergne; and this almost entirely for the indirect benefits resulting from forests to the mountains, as the plantations and embankments which form the *reboisement* works are too costly ever to yield a direct revenue commensurate with the heavy expenditure incurred in such remote and inaccessible places. If, however, Major Powell's proposed denudation of the Rocky Mountains were to be effected, besides its disastrous indirect results, America would suffer from a greatly curtailed supply of timber to meet the ever-increasing demands of a vast continent, which cannot depend on any adequate supply from abroad. We see that in the McKinley Act the Government of the United States already acknowledges its own short supply by withdrawing all import duties from Canadian timber; and it is for Canada to assure its own future prosperity by establishing a State forest service to prevent the exhaustion of the Canadian forests, now that they are likely to be fully utilized.

Up to the present time, the Forest Department of the United States has been chiefly occupied in collecting forest statistics and encouraging private planting, but what is really required is to induce each State in the Union to establish a practical control of its own still existing forests.

The Americans have recently refused to join in a postal confederation of English-speaking countries, on the ground that they are now to a large extent German-speaking as well; it is a pity, therefore, that they do not listen to the warnings of the German forester, Dr. Mayer, who has studied the forests of the Rocky Mountains and has given the last word of German scientific opinion on the utter absence of a State forest policy in the United States, in his recently published work on the forest trees of North America. Throwing-Sticks and Canoes in New Guinea.

I HAVE just received here my copy of the February number of vol. xix. of the Journal of the Anthropological Institute, in which I have read, with the greatest interest and appreciation, the long and valuable account of the western tribe of Torres Strait, by Prof. Haddon. With regard to the throwing-sticks, of which, on p. 332, he says, "the heavy spears of South-east New Guinea are hurled by a throwing-stick which differs from any Australian implement," I think some error must have been made by his informant. I never saw a throwing-stick in existence, or in use, during my three years' residence in the country, either in the interior, along the south-eastern peninsula, in the Louisiade Archipelago, or on the northern coast as far as Mitre Rock. If these implements do exist on the southern side, they must be very rare. The first spear-thrower from New Guinea brought to England, as far as I am aware, was, nevertheless, the one brought home by me in 1888, which is now in the British Museum. It came, however, from the German possessions on the north-east coast, either from Finch-haven, or from the Augusta River, if I recollect correctly, and was given to me in Cooktown.

In the same paper, on p. 384, occurs this passage with regard to canoes:—"I was much puzzled when I first went to Torres Straits by occasionally seeing a canoe with a single outrigger. I afterwards found that it belonged to a Kanaker from Ware [? Mare], one of the New Hebrides, residing at Mabuiag, and that he had outrigged a native canoe according to the fashion of his own people. When I was at Mabuiag, some natives of that island were fitting up a canoe in imitation of this one, and with a single outrigger. Here a foreign custom is being imitated." The bulk of the large canoes seen on the south-eastern coast at Motu-Motu, Port Moresby, Kerepunu, and in Milne Gulf, have no outriggers at all; while along the coast in small canoes, and in both large and small in the Louisiade Archipelago, the single outrigger is the prevailing form. It is the canoe indigenous to the region, and is undoubtedly not an introduced or imitated custom. The single outrigger in Torres Strait may be an imitation, but it is also a true New Guinea model.

Pectination.

I HAVE been somewhat disappointed to find that no one can suggest a better explanation of the pectination of birds' claws than that which I gave in NATURE of December 4, 1890 (p. 103). As this is the case, however, perhaps I may be permitted to add a remark to what I then said. It has been pointed out to me by a friend that the lateral position of the serration is not so disadvantageous for scratching purposes as I had imagined. While gladly admitting this—which removes a difficulty from the explanation—I still think that my observations must not be taken as conclusive.

It would be most useful and interesting if an observer could be found to give time and attention to representatives of the different orders of birds which possess this peculiarity.

E. B. TITCHENER.

Inselstrasse 13, Leipzig, January 7.

The Flight of Larks.

THE extraordinary flight of larks to which the Rev. E. C. Spicer refers was observed at Bournemouth. The birds appeared to come across the Channel in thousands, and in a few days had entirely disappeared. There were certainly some fieldfares among them. ALFRED W. BENNETT.

PROFESSOR VIRCHOW ON THE CONSUMPTION CURE.[1]

THE important communication made by the renowned German pathologist at the last meeting of the Berlin Medical Society is a severe shock to the opinions of those who expect that Koch's mysterious lymph will prove applicable in every case of consumption. Prof. Virchow gives the result of his observations on twenty-one cases that have died, after treatment with the lymph, up to the end of December. Since then, six or seven other cases have come under his notice, but have not yet been completely examined. Of the twenty-one cases, sixteen were phthisical. The remaining five included a case of joint tuberculosis; a case in which lung tuberculosis was accompanied with carcinoma of the pancreas; another had empyema; the next had pernicious anæmia, slight changes in the lungs, and tuberculous pleuritis; and, lastly, comes a case of tubercular inflammation of the arachnoid.

It appears, from an examination of these cases, that the lymph has an action on tuberculosis of internal organs similar to that which it has already been seen to exert on external portions of the body similarly affected. The signs of an intense irritation, such as redness and swelling, are very generally to be met with. An excellent example of this action is afforded by the above-mentioned

[1] Reported in the *Berliner klinische Wochenschrift*, January 12, 1890.

case of inflammation of the arachnoid. Death occurred after the fourth injection, and Prof. Virchow has never seen so intense a hyperæmia of the pia mater and brain as this case presented. After careful examination no regressive changes could be found in the tubercular tissues.

The inflammatory changes met with in the various cases were not confined to a simple hyperæmia, which might possibly be regarded as of a transitory nature, but tissue changes which promised to be of a more lasting nature were also to be met with. The lymph glands near the affected parts, for instance, were found to be greatly enlarged. The increase in size seems due to a rapid multiplication of the cells in the medullary part of the gland—a change which is characteristic of acute irritations. This is probably connected with the increase in the number of white blood-corpuscles that has frequently been found to follow lymph injections, and this, again, with the frequent infiltration by leucocytes of affected parts and their surrounding tissues.

The changes produced in the lungs themselves belong to two widely different categories. Firstly, comes "caseous hepatization." That this can be actually caused by the injections is rendered highly probable by a very striking case, in which infiltration only commenced after the treatment had ceased, and led to a caseous hepatization of almost unique extent. Six injections had been made on this patient, of which the last was made four weeks before his death. Secondly, a "catarrhal pneumonia" is met with, sometimes alone, sometimes accompanied by the first-mentioned change. This form of pneumonia differs from ordinary catarrhal pneumonia in that it seems to lead to a rapid destruction of the lung-parenchyma, and a sort of cavity formation.

The most important conclusion that Prof. Virchow puts forward is that the formation of new tubercles which has been met with in many of these fatal cases must be ascribed with great probability to the action of the lymph itself.

The appearance of new tubercles has already been observed in lupus and tuberculosis of the larynx. Hitherto it has been asserted that the changes in question were merely due to the action of the lymph on tubercular material latent in the apparently healthy tissues. This view appears to be no longer tenable, at any rate as a general explanation. On serous membranes, which Virchow has always regarded as being best fitted for the observation of the early stages of tuberculosis, perfectly new submiliary tubercles have been found, under conditions which make it scarcely probable that they dated from an earlier stage of the disease. All these tubercles were perfectly intact, even in cases in which the injections had been made several weeks before. There was nothing to support the suggestion that these tubercles had been in any way affected or harmed by the action of the lymph.

How can this outbreak of new tubercles be explained?

In a phthisical case which terminated fatally, four small tubercles, surrounded by a zone of well-marked hyperæmia, were found situated on a part of the pericardium that could in no way come into contact with the lungs. In this case a direct infection was impossible, and we must suppose that, owing to the action of the lymph in breaking down the tubercular masses in the lungs, tubercle bacilli were thrown into the circulation, and thus reached the pericardium, where they succeeded in producing a metastatic infection.

In consequence of these and other similar observations, Prof. Virchow comes to the conclusion that the lymph should not be employed in cases in which one would expect some difficulty in excreting the tubercular matter set free by the treatment.

In forming an opinion as to the clinical bearing of these *post-mortem* appearances, it must be borne in mind that most, if not all, of these fatal cases were already in an advanced stage before they came under treatment; and, from the practical point of view, Virchow's work merely adds to the evidence that is gradually accumulating in the Berlin clinics, of the unsuitability of Koch's lymph for advanced cases, at all events with the present methods of administration.

For other considerations arise besides that of the stage of the disease. Thus I have good reason for believing that Koch's treatment of consumption has been less successful at the Charité (in which hospital Virchow's twenty-one cases have occurred) than in the other hospitals and clinics of Berlin. It would be interesting to determine whether any difference in the details of the treatment at the various hospitals could help to explain the difference in the results. The quantities of lymph employed and the frequency of the injections are by no means uniform in the various hospitals. For example, the Charité and the Friederichshain appear to stand at the opposite ends of the scale in these respects. For the following details respecting these hospitals I am indebted to a friend, who during the last month has been studying the results in the various clinics. At the Charité the injections appear to be administered more frequently and with a more rapid increase in the size of the doses than is the custom in the Friedrichshain Hospital. Further, the largest dose administered to a patient at Friedrichshain seems almost always below that given at the Charité, whilst the average dose given at the latter hospital also seems generally larger. Naturally, it would be unwise to draw definite conclusions until the details of such a comparison have been thoroughly investigated, but whatever the explanation may be, I have good reasons for asserting that the results obtained at Friedrichshain have been far more favourable than those obtained at the Charité. Not only do the milder cases seem to have made better progress at the former hospital, but the severer cases have less often had a fatal termination.

It would thus appear as if the dosage alone has a considerable influence upon the results obtained, even in the advanced cases which alone are the subject of Prof. Virchow's animadversion.

E. H. HANKIN.

THE RESEARCHES OF DR. R. KŒNIG ON THE PHYSICAL BASIS OF MUSICAL SOUNDS.[1]

III.

A FINAL proof, if such were needed, is afforded by an experiment, which, though of a striking character, will not necessarily be heard by all persons present, being only well heard by those who sit in certain positions. If a shrill tuning-fork is excited by a blow of the steel mallet, and held opposite a flat wall, part of the waves which it emits strike on the surface, and are reflected. This reflected system of waves, as it passes out into the room, interferes with the direct system. As a result, if the fork, held in the hand be moved toward the wall or from it, a series of maxima and minima of sound will successively reach an ear situated in space at any point near the line of motion, and will be heard as a series of beats; the rapidity with which they succeed one another being proportional to the velocity of the movement of the fork. The fork Dr. Kœnig is using is ut_6, which gives well-marked beats, slow when he moves his arm slowly, quick when he moves it quickly. There are limits to the speed at which the human arm can be moved, and the quickest speed that he can give to his fails to make the beats blend to a tone. But if he will take sol_6, vibrating $1\frac{1}{2}$ times as fast, and strike it, and move it away from the wall with the fastest speed that his arm will permit, the

[1] By Prof. Silvanus P. Thompson. (Communicated by the author having been read to the Physical Society of London, May 16, 1890.) Continued from p. 227.

beats blend into a short low growl, a non-uniform tone of low pitch, but still having true continuity.

This first portion of my account of Dr. Kœnig's researches may then be summarized by saying that in all circumstances where beats, either natural or artificial, can be produced with sufficient rapidity, they blend to form a beat-tone of a pitch corresponding to their frequency.

I now pass to the further part of the researches of Dr. Kœnig which relates to the timbre of sounds. Prior to the researches of Dr. Kœnig, it had been supposed that in the reception by the ear of sounds of complex timbre the ear took no account of, and indeed was incapable of perceiving, any differences in phase in the constituent partial tones. For example, in the case of a note and its octave sounded together, it was supposed and believed that the sensation in the ear, when the difference in phase of the two components was equivalent to one-half of the more rapid wave, was the same as when that difference of phase was one-quarter, or three-quarters, or zero. I had myself, in the year 1876, when studying some of the phenomena of binaural audition, shown reason for holding that the ear does nevertheless take cognizance of such differences of phase. Moreover, the peculiar rolling or revolving effect to be noticed in slow beats is a proof that the ear perceives some difference due to difference of phase. Dr. Kœnig is, however, the first to put this matter on a distinct basis of observations. That such differences of phase occur in the tones of musical instruments is certain: they arise inevitably in every case where the sounds of subdivision are such that they do not agree rigidly with the theoretical harmonics. Fig. 5 depicts a graphic record taken by Dr. Kœnig from a vibrating steel wire, in which a note and its octave had been simultaneously excited. The two sounds were scarcely perceptibly different from their true interval, but the higher note was just sufficiently sharper than the true harmonic octave to gain about one wave in 180. The graphic trace has in Fig. 5 been split up into 5 pieces to facilitate insertion in the text. It will be seen that as the phase gradually changes the form of the waves undergoes a slow change from wave to wave. Now, it is usually assumed that in the vibrations of symmetrical systems, such as stretched cords and open columns of air, the sounds of subdivision agree with the theoretical harmonics. For example, it is assumed that when a stretched string breaks up into a nodal vibration of four parts, each of a quarter its length, the vibration is precisely four times as rapid as the fundamental vibration of the string as a whole. This would be true if the string were absolutely uniform, homogeneous, and devoid of rigidity. Strings never are so; and even if uniform and homogeneous, seeing that the rigidity of a string has the effect of making a short piece stiffer in proportion than a long piece, cannot emit true harmonics as the sounds of subdivision. In horns and open organ-pipes the width of the column

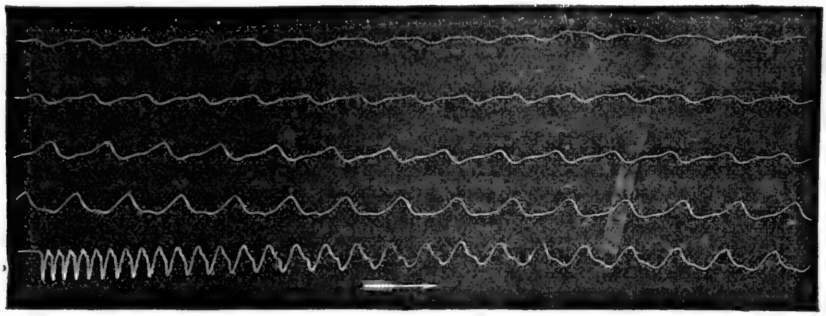

Fig. 5.

(which is usually neglected in simple calculations) affects the frequency of the nodal modes of vibration. Wertheim found the partial tones of pipes higher than the supposed harmonics.

These things being so, it is manifestly insufficient to assume, as von Helmholtz does in his great work, that all timbres possess a purely periodic character; with the necessary corollary that all timbres consist merely in the presence, with greater or less intensity, of one or more members of a series of higher tones corresponding to the terms of a Fourier series of harmonics. When, therefore, following ideas based on this assumption, von Helmholtz constructs a series of resonators, accurately tuned to correspond to the terms of a Fourier series (the first being tuned to some fundamental tone, the second to one of a frequency exactly twice as great, the third to a frequency exactly three times, and so forth), and applies such resonators to analyze the timbres of various musical and vocal sounds, he is trying to make his resonators pick up things which in many cases do not exist—upper partial tones which are exact harmonics. If they are not exact harmonics, even though they exist, his tuned resonator does not hear them, or only hears them imperfectly, and he is thereby led into an erroneous appreciation of the sound under examination.

Further, when in pursuance of this dominant idea he constructs a system of electro-magnetic tuning-forks, accurately tuned to give forth the true mathematical harmonics of a fixed series, thinking therewith to reproduce artificially the timbres not only of the various musical instruments but even of the vowel sounds, he fails to reproduce the supposed effects. The failure is inherent in the instrument; for it cannot reproduce those natural timbres which do not fall within the circumscribed limits of its imposed mathematical principle.

Nothing is more certain than that in the tones of instruments, particularly in those of such instruments as the harp and the pianoforte, in which, the impulse, once given, is not sustained, the relations between the component partial tones are continually changing, both in relative intensity and in phase. The wavelets, as they follow one another, are ever changing their forms: in other words, the motions are not truly periodic—their main forms may recur, but with modifications ever changing.

To estimate the part played in such phenomena by mere differences of phase—to evaluate, in fact, the influence of phase of the constituents upon the integral effect of a compound sound—Dr. Kœnig had recourse to the *wave-siren*, an earlier invention of his own, and of which the wave-disks which have already been shown are examples.

In the first place, Dr. Kœnig proceeded synthetically to construct the wave-forms for tones consisting of the resultant of a set of pure harmonics of gradually decreasing intensity. The curves of these, up to the tenth member of the series, were carefully compounded graphically: first with zero difference of phase, then with all the upper members shifted on one quarter, then with a difference of a half-wave, then with a difference of three-quarters. The results are shown in the top line of curves in Fig. 6, wherein it will be noticed that the curve for difference of phase = $\frac{1}{2}$ is like that for zero difference, but reversed, left for right; and that the curve for difference of phase = $\frac{3}{4}$ is like that for difference = $\frac{1}{4}$, but inverted. Now, according to von Helmholtz, the sounds of all these four curves should be precisely alike, in spite of their differences of form and position. To test the matter, these carefully-plotted curves were set out upon the circumference of a cylindrical band of thin metal, the edge being then cut away, leaving the unshaded portion, the curve being repeated half a dozen times, and meeting itself after passing round the circumference. For convenience, the four curves to be compared are set out upon the separate rims of two such metallic cylindrical hoops, which are mounted upon one axis, to which a rapid motion of rotation can be imparted, as shown in Fig. 7. Against the dentellated edges of these rims, wind can be blown through narrow slits connected to the wind-chamber of an organ-table. In the apparatus (Fig. 7) the four curves in question are the four lowest of the set of six. It will be obvious that, as these curves pass in front of the slits from which wind issues, the maximum displacement of air will result when the slit is least covered, or when the point of greatest depression of the curve crosses the front of the slit. The negative ordinates of the curve correspond, therefore, approximately to condensations. Air is now being supplied to the slits; and when I open one or other of the valves which control the air-passages, you hear one or other of the sounds. It must be audible to everyone present that the sound is louder and more forcible with a difference of phase of $\frac{1}{4}$ than in any other case, that produced with $\frac{3}{4}$ difference being gentle and soft in tone, whilst the curves of phase 0 and $\frac{1}{2}$ yield tones of intermediate quality. Dr. Kœnig found that, if he merely combined together in various phases a note and its octave (which was indeed the instance examined by me binaurally in 1876), the loudest resultant sound is given when the phase-difference of the combination is $\frac{1}{4}$, and the mildest when it is $\frac{3}{4}$.

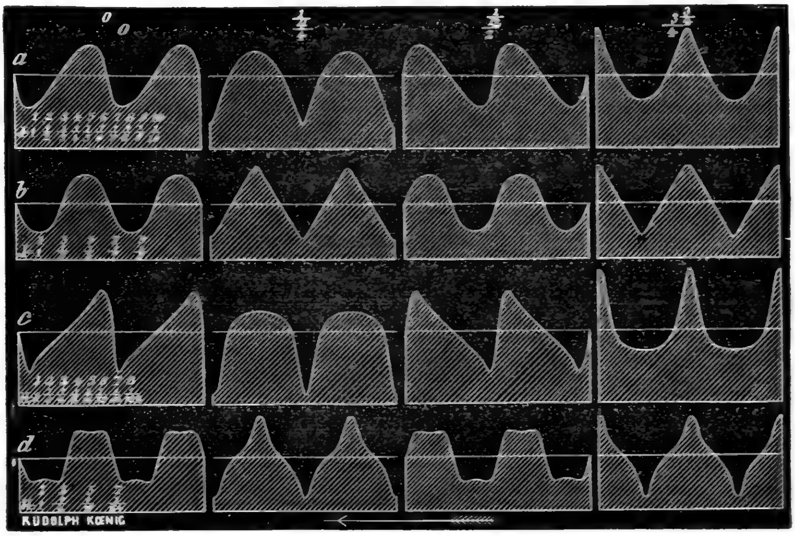

FIG. 6.

FIG. 7.

Returning to Fig. 6, in the second line are shown the curves which result from the superposition of the odd members only of a harmonic series of decreasing amplitude. On comparing together the curves of the four separate phases, it is seen that the form is identical for phases 0 and $\frac{1}{2}$, which show rounded waves, whilst for phases $\frac{1}{4}$ and $\frac{3}{4}$ the forms are also identical, but with sharply angular outline. These two varieties of curve are set out on the two edges of the highest metallic circumference in the apparatus depicted in Fig. 7. The angular waves are found to yield a louder and more strident tone than the rounded waves, though, according to von Helmholtz, their tones should be alike.

A much more elaborate form of compound wave-siren was constructed by Dr. Kœnig for the synthetic study of these phase-relations. Upon a single axis, one behind the other is mounted a series of 16 brass disks, cut at their edges into sinusoidal wave-forms. These represent a harmonic series of 16 members of decreasing amplitude, there being just 16 times as many small sinuosities on the edge of the largest disk as there are of large sinuosities on that of the smallest disk. A photograph of the apparatus is now thrown upon the screen. It is described fully by Dr. Kœnig in his volume "Quelques Expériences," and was figured and described in NATURE, vol. xxvi. p. 277. Against the edge of each of the 16 wave-disks wind can be separately blown through a slit. This instrument therefore furnishes a fundamental sound with its first fifteen pure harmonics. It is clear that any desired combination can be obtained by opening the appropriate stops on the wind-chest; and there are ingenious arrangements to vary the phases of any of the separate tones by shifting the positions of the slits. The following are the chief results obtained with this instrument. If we first take simply the fundamental tone and its octave together, the total resultant sound has the greatest intensity when the difference of phase $\delta = \frac{1}{4}$ (*i.e.* when the maximum displacement of air occurs at the same instant for both waves); and at the same time the whole character of the sound becomes somewhat graver, as if the fundamental tone predominated more than in other phases. The intensity is least when $\delta = \frac{3}{4}$. If, however, attention is concentrated on the octave note while the phase is changed, its intensity seems about the same for $\delta = \frac{1}{4}$ as for $\delta = \frac{3}{4}$, but weaker in all other positions. The compound tones formed only of odd members of the series have always more power and brilliancy of tone for phase differences of $\frac{1}{4}$ and $\frac{3}{4}$, than for 0 and $\frac{1}{2}$; but the quality for $\frac{1}{4}$ is always the same as for $\frac{3}{4}$, and the quality for 0 is always the same as for $\frac{1}{2}$. This corresponds to the peculiarity of the corresponding wave-form, of which the fourth line of curves in Fig. 6 is an example. For compound tones corresponding to the whole series, odd and even, there is, in every case, minimum intensity, brilliancy, and stridence with $\delta = \frac{3}{4}$, and maximum with $\delta = \frac{1}{4}$. Inspection of the first and third lines of curves in Fig. 6 shows that in these wave-forms that phase which is the most forcible is that in which the maximum displacement, and resulting condensation, is sudden and brief.

Observing that wave-forms in which the waves are asymmetrical—steeper on one side than on the other—are produced as the resultant of a whole series of compounded partial tones, it occurred to Dr. Kœnig to produce from a perfect and symmetrical sinusoidal wave-curve a complex sound by the very simple device of turning into an oblique position the slit through which the wind was blown against it. In Fig. 8 is drawn a simple sym-

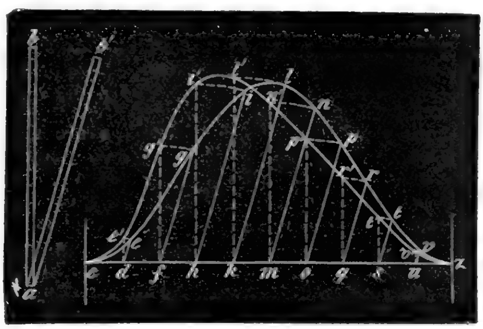

FIG. 8.

metrical wave-form, *eglnprtv*. If a series of such wave-forms is passed in front of a vertical slit, such as *ab*, a perfectly simple tone, devoid of upper partials, is heard. But by inclining the slit, as at *ab'*, the same effect is produced as if the wave-form had been changed to the oblique outline *e'g'l'n'p'r't'v'*, the slit all the while remaining upright. But this oblique form is precisely like that obtained as resultant of a decreasing series of partial tones (Fig. 6, *a*). If the slit be inclined in the same direction as the forward movement of the waves, the quality produced is the same as if all the partial tones coincided at their origin, or with $\delta = 0$; while if inclined in the opposite direction the quality is that corresponding to $\delta = \frac{1}{2}$. It is easy to examine whether the change of phase produces any effect on the sound. Before you is rotating a simple wave-disk, and air is being blown across its edge through a slit. Dr. Kœnig will now tilt the slit alternately backward and forward. On tilting the slit forward to give $\delta = 0$, you hear a purer and more perfect sound; and on tilting it back, giving $\delta = \frac{1}{2}$, a sound that is more nasal and forcible.

All the preceding experiments agree then in showing that differences of phase do produce a distinct effect upon the quality of compound tones: what then must we say as to the effect on the timbre of the presence of upper partial tones or sounds of subdivision that do not agree with any of the true harmonics? A mistuned harmonic—if the term is permissible—may be looked upon as a harmonic which is undergoing continual change of phase. The mistuned octave which yielded the graphic curve in Fig. 5 is a case in point. The wavelets are continually changing their form. It is certain that in a very large number of musical sounds, instrumental and vocal, such is the case.

It was whilst experimenting with his large compound wave-siren that Dr. Kœnig was struck by the circumstance that under no conditions, and by no combination of pure harmonics in any proportion of intensity or phase, could he reproduce any really strident timbres of sound, like those of harmonium reeds, trumpets, and the like; nor could he produce satisfactory vowel qualities of tone. Still less can these be produced satisfactorily by von Helmholtz's apparatus with electro-magnetic tuning-forks, in which there is no control over the phases of the components. The question was therefore ripe for investigation whether for the production of that which the ear can recognize as a *timbre*, a definite unitary quality of tone, it was necessary to suppose that all the successive wavelets should be of similar form. Or, if the forms of the successive wavelets are continually changing, is it possible for the ear still to grasp the result as a unitary sensation?

If the ear could always separate impure harmonic or absolutely inharmonic partials from their fundamental tone, or if it always heard pure harmonics as an indistinguishable part of the unity of the timbre of a fundamental, then we might draw a hard and fast line between mere mixtures of sound and timbres, even as the chemist distinguishes between mere mixtures and true chemical compounds. But this is not so: sometimes the ear cannot unravel from the integral sensation the inharmonious partial; on the other hand, it can often distinguish the presence of truly harmonious ones. Naturally, something will depend on the training of the ear; as is the case with the conductor of an orchestra, who will pick out single tones from a mixture of sounds which to less perfectly trained ears may blend into a unitary sensation.

Dr. Kœnig accordingly determined to make at least an attempt to determine synthetically how far the ear can so act, by building up specific combinations of perturbed harmonics or inharmonic partials, giving rise to waves that are multiform, as distinguished from the uniform waves of a true periodic motion. The wave-siren presented a means of carrying this attempt to a result. On the table before me lie a number of wave-disks constructed with this aim. This will be successively placed upon the whirling table, and sounded: but I must warn you that the proper effects will only be perceived by those who are near the apparatus, and in front of it.

Upon the edge of the first of the series there has been cut a curve graphically compounded of 24 waves as a fundamental, together with a set of four perturbed harmonics of equal intensity. The first harmonic consists of 49 waves (2 × 24 plus 1); the second of 75 waves

(3 × 24 plus 3); the third of 101 (4 × 24 plus 5); the fourth of 127 (5 × 24 plus 7). The resulting curve possesses 24 waves, no two of them alike in form, and some highly irregular in contour. The effect of blowing air through a slit against this disk is to produce a disagreeable sound, quite lacking in unitary character, and indeed suggesting intermittence.

The second wave-disk is constructed with the same perturbed harmonics, but with their amplitudes diminishing in order. This disk produces similar effects, but with more approach to a unitary character.

In the third disk there are also 24 fundamental waves, but there are no harmonics of the lower terms, the superposed ripples being perturbed harmonics of the fifth, sixth, and seventh orders. Their numbers are 6 × 24 plus 6; 7 × 24 plus 7; and 8 × 24 plus 8; being, in fact, three harmonics of a fundamental 25. This disk gives a distinctly dual sort of sound; for the ear hears the fundamental quite separate from the higher tones, which seem in themselves to blend to a unitary effect. There is also an intermittence corresponding to each revolution of the disk, like a beat.

The fourth disk resembles the preceding; but the gap between the fundamental and the three perturbed harmonics has been filled by the addition of three true harmonics. This disk is the first in this research which gives a real timbre, though it is a peculiar one: it preserves, however, a unitary character, even when the slit is tilted in either direction. The 24 waves in this disk all rake forward like the teeth of a circular saw, but with multiform ripples upon them. The quality of tone becomes more crisp when the slit is tilted so as to slope across the teeth, and more smooth when in the reverse direction.

The fifth disk, which is larger, has 40 waves at its edge; these are cut with curves of all sorts, taken hap-hazard from various combinations of pure harmonics in all sorts of proportions and varieties, no two being alike, there maxima and minima of the separate waves being neith isochronous nor of equal amplitude. This disk gives an entirely unmusical effect, amid which a fundamental tone is heard, accompanied by a sort of rattling sound made up of intermittent and barely recognizable tones.

The sixth disk is derived from the preceding by selecting eight only of the waves, and repeatiug them five times around the periphery. In this case each set of eight acts as a single long curve, giving beats, with a slow rotation, and a low tone (accompanied always by the rattling mixture of higher tones) when the speed is increased.

The seventh disk was constructed by taking 24 waves of perfect sinusoidal form, and superposing upon them a series of small ripples of miscellaneous shapes and irregular sizes, but without essentially departing from the main outline. This disk gives a timbre in which nothing can be separated from the fundamental tone, either with vertical or tilted slit.

The eighth and last disk consists of another set of 24 perfect waves, from the sides of which irregular ripples have been carved away by hand, with the file, leaving, however, the summits and the deepest parts of the hollows untouched, so that the maxima and minima are isochronous and of equal amplitude. This disk gives also a definite timbre of its own, a little raucous in quality, but still distinctly having a musical unity about it.

We have every reason, therefore, to conclude that the ear will recognize as possessing true musical quality, as a timbre, combinations in which the constituents of the sound vary in their relative intensity and phase from wave to wave.

What, then, is *a timbre?* Dr. Kœnig would be the first to recognize that these last experiments, though of deepest interest, do not afford a final answer to the question. We may not yet be in a position to frame a new definition as to what constitutes a timbre, but we may at least conclude that, whenever that definition can be framed, it will at least include several varieties, including the non-periodic kinds with multiform waves, as well as those that are truly periodic with uniform waves. We must not on that account, however, rush to the conclusion that the theory of von Helmholtz as to the nature of timbre has been overthrown. The corrections introduced into lunar theory by Hansen and Newcomb have not overturned the splendid generalizations of Newton. What we can and must confess is that we now know that the acoustic theory of von Helmholtz is, like the lunar theory of Newton, correct only as a first approximation. It has been the distinctive merit of Dr. Kœnig to indicate to us the magnitude of the correcting terms, and to supply us not only with a rich store of experimental facts but with the means of prosecuting the research synthetically beyond the point to which he himself has attained.

In thanking Dr. Kœnig for the courtesy which he has shown to this Society in bringing over his apparatus and in demonstrating its use to us, we must join in congratulating him on the patience, perspicacity, and skill with which he has carried out his researches. We know that his exceptional abilities as experimentalist and constructor have done more than those of any other investigator to make the science of experimental acoustics what it is to-day; and we must unite in wishing him long life and prosperity to complete the great work on which already he has advanced so far.

THE GEOLOGY OF ROUND ISLAND.

BOTANISTS have been a little perplexed as to the exact geological age of some of the islands in the Indian Ocean, and the current statements on the subject are by no means accordant. Any exact information on the subject seems, therefore, worth placing on record.

Round Island is a minute island, about two miles in diameter, which lies north-east of Mauritius, and about 13 miles distant. It was visited last November by Mr. William Scott, Assistant to the Director of Forests and Botanical Gardens, Mauritius, accompanied by Surgeon H. H. Johnston.

There is only one point where landing can be effected in calm weather; the end of November was therefore chosen for the visit as being the best season for landing. Unfortunately, the season at this time was very dry, so that the whole of the vegetation was in a dormant state, and little could be done in the way of procuring good specimens.

"The only trees," Mr. Scott writes, "of any size to be found on the island, are the Palms:—*Latania Loddigesii*, *Hyophorbe amaricaulis*, *Dictyosperma alba*, var. *aurea*, and the screw-pine *Pandanus Vandermeeschii*. These trees look stunted, and grow in clumps mixed up together where any root-hold is to be found. There were only at that time two or three grasses to be found, and these were in a very dry state. One or two Passifloras [probably introduced] and *Asclepiadaceæ* were also found. On these two latter, the wild goats which inhabit the island in hundreds, appear to exist."

Mr. Scott made a very careful collection of the rocks composing the island. His specimens were sent to Kew and were submitted to Prof. Judd, F.R.S., who very kindly examined them. He furnished me with the following report, which he has kindly allowed me to publish. W. T. Thiselton Dyer.

Royal Gardens, Kew, December 4.

Science Schools, South Kensington, S.W., September 29.

My dear Dyer,—Immediately upon my return to town I have, as I promised you, examined the specimens from Round Island, with the notes on the same by Mr. Scott. My conclusions are as follows:—

The rocks of the island appear to be entirely of organic or volcanic origin.

The lower part of the island consists of a limestone made up of shell and coral (?) detritus, cemented into a hard and crystalline rock (see specimens 1, 3, 15). Masses of this rock of greater hardness than usual seem to have resisted denudation, and stand up as pinnacles among the overlying stratified tuffs (specimen 14). Fissures in the various rocks are filled with a stalagmitic deposit of calcic carbonate (specimen 8). But the great mass of the island would appear to be made up of stratified *palagonite tuffs*, some coarse-grained, others very fine-grained. These palagonite tuffs, which closely resemble the similar rocks in Sicily and Iceland, are very beautiful and interesting varieties; and, besides the hydrous basic glass known as palagonite, contain various beautiful zeolites and other minerals (specimens 4, 5, 6, 7, 9, 10, 11, 12).

The lavas associated with these tuffs appear to occur both as ejected blocks and in lava-currents, and consist of a highly scoriaceous basalt rich in olivine (specimens 2 and 13).

These are the general facts concerning the structure of the island which are revealed by a general examination of the specimens with Mr. Scott's interesting notes.

I return these last with this letter. The specimens I retain for the present, as some among them will, I think, repay a minuter study than I have yet been able to afford time for. JOHN W. JUDD.

NOTES.

THE Medals and Funds to be given at the anniversary meeting of the Geological Society of London on February 20 have been awarded by the Council as follows: the Wollaston Medal to Prof. J. W. Judd, F.R.S.; the Murchison Medal to Prof. W. C. Brögger, of Christiania; the Lyell Medal to Prof. T. McKenny Hughes, F.R.S.; and the Bigsby Medal to Dr. G. M. Dawson; the balance of the Wollaston Fund to Mr. R. Lydekker; that of the Murchison Fund to Mr. R. Baron; and portions of the Lyell Fund to Messrs. C. J. Forsyth Major and G. W. Lamplugh.

AT the meeting of the Institution of Civil Engineers on Tuesday, M. Carnot, President of the French Republic, was elected an honorary member.

THE forty-fourth annual general meeting of the Institution of Mechanical Engineers will be held on Thursday evening, January 29, and Friday evening, the 30th, at 25 Great George Street, Westminster. The chair will be taken by the President, Mr. Joseph Tomlinson, at half-past seven p.m. on each evening. After the presentation of the annual report, and the transaction of other business, the following papers will be read and discussed, as far as time permits:—On some different forms of gas furnaces, by Mr. Bernard Dawson, of Malvern; on the mechanical treatment of moulding sand, by Mr. Walter Bagshaw, of Batley; fourth report of the research committee on friction: experiments on the friction of a pivot bearing.

THE Royal Microscopical Society will hold its annual meeting on Wednesday evening, the 21st inst., at 8 o'clock. The President will deliver an address.

THE annual general meeting of the Royal Meteorological Society will be held at 25 Great George Street, Westminster, on Wednesday, the 21st inst., at 8.15 p.m. It will be preceded by an ordinary meeting, beginning at 7 p.m., at which the following papers will be read:—Note on a peculiar development of cirrus cloud observed in Southern Switzerland, by Mr. Robert H. Scott, F.R.S.; and some remarks on dew, by Colonel W. F. Badgley, F.R.Met.Soc.

THE Council of the Royal Meteorological Society have arranged to hold at 25 Great George Street, Westminster, from March 17 to 20, an Exhibition of rain gauges, evaporation gauges, percolation gauges, and kindred instruments. The Exhibition Committee invite co-operation in this undertaking. They will also be glad to show any new meteorological instruments or apparatus invented, or first constructed, since last March; as well as photographs and drawings possessing meteorological interest. Anyone willing to co-operate in the proposed Exhibition should furnish Mr. William Marriott, the Secretary, not later than February 10, with a list of the articles he will be able to contribute, and an estimate of the space they will require.

THE Sanitary Institute has made arrangements for a course of sixteen lectures for the special instruction of those who may wish to obtain knowledge of the duties of sanitary officers. These lectures, which will be a continuation of previous courses, will be delivered at the Parkes Museum, and will be illustrated with diagrams, drawings, and models. The first lecture will be given on January 30 by Sir Douglas Galton, who will deal with ventilation, warming, and lighting. Among the other lecturers will be Mr. H. Law, Dr. Louis Parkes, and Prof. W. H. Corfield.

DR. SYMES THOMPSON will deliver at Gresham College, on January 20 and the three following days, a course of four lectures on the preservation of health. He will deal with questions relating to healthy homes, healthy schools, and the early detection and prevention of disease.

MR. A. SIDNEY OLLIFF, late assistant in the Museum, Sydney, has been appointed to the newly-instituted office of Government Entomologist in the Department of Agriculture, New South Wales. His duties will be chiefly the study of insects affecting fruits and crops, whether injurious or beneficial, and publishing reports on the results for the information of farmers and horticulturists. According to the latest news as to the new insect pest, Mr. Olliff will not lack employment.

M. PATOUILLARD has been elected President, and MM. Prillieux and de Seynes, Vice-Presidents, of the Société Mycologique de France.

THE death is announced of M. Clavaud, Professor of Botany at Bordeaux, author of the "Flora de la Gironde," of which two parts only have appeared, embracing the *Thalamifloræ* and the *Calycifloræ*. The work is characterized by its beautiful plates, and by the attempts to place on a scientific basis the genetic relationship of the various species with one another.

MR. GEORGE W. ORMEROD, of Teignmouth, died on January 6, at the age of eighty. He had been a member of the Geological Society of London for fifty-eight years, and geologists owe much to him for his classified index to the *Quarterly Journal* and other publications.

ACCORDING to a telegram from Rusk, Texas, two sharp earthquake shocks were felt there on January 8. Chimneys were thrown to the ground, and people awakened by the violence of the oscillations.

AT the meeting of the French Meteorological Society on December 2, M. Angot communicated the results of comparisons of the pressure and temperature observations at the Eiffel Tower during 1889 with the low-level stations. The night maxima and minima of pressure are less marked on the Tower than at the lower levels, as is also the case with mountain observations, and inversely for the day maxima and minima. For individual readings small variable differences were found between the actual pressure at the summit and the pressure calculated from observations at the base. Generally, during rapid falls of the barometer, the true pressure at the summit is lower than the calculated value, and higher when the barometer is rising. The temperature observations will be referred to subsequently. At the meeting of December 16 a discussion took place upon the trustworthiness of aneroid barometers, owing to their not always immediately returning to their original condition after a sudden rise or fall. The balance of opinion was in their favour. M. Doumet-Adanson communicated an account of a tornado at Fourchambault on October 1, 1890. Its sudden appearance there is supposed to be due to one of a series of bounds and rebounds which these meteors are sometimes reported to make. M. Angot was elected President of the Society for the ensuing year.

La Nature of January 3 describes a useful recording barometer brought out by MM. Redier and Meyer. In the upper part of a case with glass front is an aneroid, the elastic cover of which is connected with a metallic slip projecting over rotated paper below. At the end of this slip is a conical ink-holder with perforated point. Three times in the hour this descends to make a dot on the paper, and the dots form a curve of the variations of pressure. The instrument goes eight days without needing attention. For observers who do not want to keep a long record, but merely to compare the variations of the day with those of a few days previous, a recording cylinder with smooth white surface is supplied, on which the record can be wiped out. This number of *La Nature* has also an account of a new steam carriage for ordinary roads, which appears to work satisfactorily.

IN his presidential address to the Queensland Royal Society, delivered on November 22, 1890, Mr. W. Saville-Kent spoke strongly in favour of the establishment of a well-appointed zoological station and marine biological laboratory in Queensland. The best site, he said, would be Thursday Island. Situated in Torres Straits, at a distance of twenty miles only from Cape York Peninsula, with a climate far more temperate than that of the mainland, and serving as a weekly or bi-weekly port of call to various lines of mail-steamers, this island is "a perfect paradise for the naturalist." In it is the central depot of the Torres Straits pearl and pearl-shell and the *bêche-de-mer* fisheries. Mr. Saville-Kent is of opinion that the acquirement of accurate knowledge concerning these products, with the application of approved methods of scientific culture, would very soon immensely increase their export value.

IN the current number of the *Revue Scientifique*, M. Hermann Fol has an interesting paper on what he calls the resemblances between husband and wife. The fact that such resemblances are not uncommon has often been noted, but the usual idea is that when they occur they are to be explained by the influence which husband and wife exert on one another in the course of years. M. Fol, however, maintains that in a large number of cases there is a more or less striking likeness from the beginning; and he draws the conclusion that in such instances the mutual attraction which leads to marriage is due to the qualities the lovers have in common, not to those in which they differ. His attention was first directed to the subject in Nice, which is visited by many newly-married people. He was so struck by the resemblances which he observed, or thought he observed, that he obtained the photographs of 251 couples who were not personally known to him, and in each case carefully noted the appearance of husband and wife. The general results he presents as follows:—

Couples.	Resemblances.		Non-resemblances.		Total.
		Per cent.		Per cent.	
Young ...	132 :	about 66·66 ...	66 :	about 33·33 ...	198
Old ...	38 :	,, 71·70 ...	15 :	,, 28·30 ...	53

THE Russian painter Krilof has for some time been engaged in painting the portraits of typical representatives of the various races included in the Russian Empire. In carrying out his purpose, he has undertaken many long journeys; and he has now a small gallery which ought to be of considerable value from an anthropological as well as from an artistic point of view. In the current number of *Globus* there is a good reproduction of one of these portraits. It represents with much force and insight a Kasak-Kirghiz.

THE director of the central dispensary at Bagdad has sent to *La Nature* a specimen of an edible substance which fell during an abundant shower in the neighbourhood of Merdin and Diarbékir (Turkey in Asia) in August 1890. The rain which accompanied the substance fell over a surface of about ten kilometres in circumference. The inhabitants collected the "manna," and made it into bread, which is said to have been very good and to have been easily digested. The specimen sent to *La Nature* is composed of small *sphérules*; yellowish on the outside, it is white within. Botanists who have examined it say that it belongs to the family of lichens known as *Lecanora esculenta*. According to Decaisne, this lichen, which has been found in Algeria, is most frequently met with on the most arid mountains of Tartary, where it lies among pebbles from which it can be distinguished only by experienced observers. It is also found in the desert of the Kirghizes. The traveller Parrot brought to Europe specimens of a quantity which had fallen in several districts of Persia at the beginning of 1828. He was assured that the ground was covered with the substance to the height of two decimetres, that animals ate it eagerly, and that it was collected by the people. In such cases it is supposed to have been caught up by a waterspout, and carried along by the wind.

MR. E. W. CARLIER writes in the current number of the *Entomologist* that one of the most remarkable features of the entomological record of 1890 was the extraordinary abundance of autumn larvæ. In a garden in Norwich, where he was staying during the month of September, everything was infested with larvæ, even to the ferns, which were in many cases almost entirely stripped of their green parts. The many-coloured larvæ of *Orgyia antiqua* (the common vapourer) were by far the most abundant, proving a perfect nuisance by their curious habit of constantly flinging themselves to the ground, from a wisteria arbour which spans the path. What could induce the insects to act in this manner he was unable to ascertain, as there was nothing but an iron garden-seat and the pebbles of the path to tempt them. This falling was not produced by wind or birds, or any other obvious cause, for, during perfect stillness of all their surroundings, they would fall by dozens upon the unfortunate occupants of the garden-chair. Nor was the habit confined to any particular age or period of the larva's existence, for among those that fell were small, large, and intermediate-sized individuals. Moreover, this habit caused a great mortality among them, for they were no sooner fairly down than they began to make for a white-washed wall which forms one boundary of the path, and attempt to climb up again to the arbour from which they fell. It so happened that many small garden spiders had elected to weave their webs from this wall to the iron framework of the arbour, and as the larvæ came to this part of their journey they often became entangled in the webs, were captured, and preyed upon by the small spiders.

THE *Zoologist* for January contains an interesting paper, by Messrs. W. E. Clarke and E. H. Barrett-Hamilton, on the Irish rat, which is "a melanistic form of *Mus decumanus*." The authors point out that this creature has a peculiar geographical distribution. In Ireland it is widely distributed, and not rare. The only known British localities in which it occurs are in the Outer Hebrides, where it has long been known to the inhabitants, and whence the authors have examined three specimens. It would appear to be quite unknown on the mainland of Britain, where all their endeavours to procure specimens have failed, though they would not be surprised to hear of the occurrence of a melanism of so common a creature as the brown rat. On the continent of Europe the only instance of the occurrence of black varieties of *Mus decumanus* known to the authors is the one recorded by A. Milne-Edwards (*Ann. Sci. Nat.*, 1871, xv. art. 7) for Paris, where, in 1871, it had been known for twenty years in the menagerie of the Museum, and is described as abundant and increasing in numbers.

PROF. J. MARK BALDWIN, writing in *Science* on "infant psychology," points out that this branch of inquiry has the great advantage of offering opportunities for the use of the experimental method. In experimenting on adults, psychologists are confronted with the difficulty that reactions are broken at the centre, and closed again by a conscious voluntary act. The subject hears a sound, identifies it, and presses a button. What goes on between the advent of the incoming nerve process and the discharge of the outgoing nerve process? Something, at any rate, which represents a brain process of great complexity. Anything that fixes this sensori-motor connection, or simplifies the central process, in so far gives greater certainty to the results. For this reason, experiments on reflex reactions are valuable and decisive where similar experiments on voluntary reactions are uncertain and of doubtful value. The fact that the child consciousness is relatively simple, and so offers a field for more fruitful experiment, is seen in the mechanical reactions of an infant to strong stimuli, such as bright colours. Of course, this is the point where originality may be exercised in the devising and executing of experiments. After the subject is a little better developed, new experimentation will be as difficult here as in the other sciences; but at present the simplest phenomena of child life and activity are open to the investigator.

THE "Year-book of Pharmacy" has just been published. It contains abstracts of papers relating to pharmacy, materia medica, and chemistry, contributed to British and foreign journals from July 1, 1889, to June 30, 1890; with the transactions of the British Pharmaceutical Conference at the twenty-seventh annual meeting, held at Leeds in September 1890. The volume has been carefully compiled, and presents a great mass of scientific information. Its utility is greatly increased by a full index.

MESSRS. IMRAY AND SON have issued, for the use of candidates preparing for the Board of Trade examinations, a syllabus of examination in the laws of compass deviation and in the means of compensating it, with explanatory notes and answers, by W. H. Rosser. The paper was written as an appendix to the author's "Deviation of the Compass, considered practically."

MESSRS. DULAU AND CO. have issued a catalogue of zoological and palæontological works which they are offering for sale. The list includes many valuable books.

THE cadmium and magnesium analogues of zinc methide and ethide have been prepared and investigated by Dr. Löhr in the laboratory of Prof. Lothar Meyer at the University of Tübingen, and an account of the work is published in the latest number of *Liebig's Annalen*. The alkyl compounds of cadmium and magnesium have formed the subject of several previous researches, but the results hitherto obtained have been mainly negative, and nothing was known with certainty concerning them. The methide and ethide of cadmium are liquid bodies, spontaneously inflammable when gently warmed. The similar compounds of magnesium are, contrary to expectation, solid substances, which possess the almost unique property of being spontaneously inflammable in carbon dioxide gas, as well as in air, being capable of actually extracting oxygen from its most stable combination with carbon. Cadmium methide was obtained by the following process:—Metallic cadmium, either in filings or pieces of sticks, was placed in a tube closed at one end together with a thin glass bulb containing methyl iodide. The tube was exhausted by the Sprengel pump and sealed. It was then heated to 110° C. for 24 hours. At the end of this time all the methyl iodide had disappeared, and the tube contained a crystalline mixture of cadmium iodide and cadmium methyl iodide, $Cd(CH_3)I$, and gaseous ethane, C_2H_6, at high pressure. After opening the tube so as to permit of the escape of the ethane, the crystalline residue was subjected to dry distillation; when the temperature of the paraffin bath in which the tube was heated reached 260° a small quantity of a liquid distilled over, and was caught in a receiver filled with carbon dioxide. Ten similar experiments were made, and the total product of this liquid was fractionally distilled in a small apparatus also filled with carbon dioxide. By this means the greater part of the admixed methyl iodide was removed, and a heavy residual liquid obtained which was found to consist mainly of cadmium methide, $Cd(CH_3)_2$. Cadmium methide is a clear heavy liquid of most unpleasant odour, violently affecting the respiratory organs, and producing a most persistent nauseous metallic taste in the mouth. It boils at about 105° C. On gently warming it spontaneously inflames, burning with a brilliant sooty flame producing thick clouds, which, according to the amount burnt, take a dark green or a reddish-brown tint. It oxidizes very rapidly to a white mass of ethylate, $Cd(OCH_3)_2$. It reacts most violently with water, producing great heat, and evolving marsh gas. Dilute hydrochloric acid acts similarly, methane being evolved and cadmium chloride formed:

$$Cd(CH_3)_2 + 2H_2O = Cd(OH)_2 + 2CH_4;$$
$$Cd(CH_3)_2 + 2HCl = CdCl_2 + 2CH_4.$$

The liquid solidifies to a white crystalline mass when the vessel containing it is immersed in a freezing mixture. Cadmium ethide is prepared with greater difficulty than the methide. It is a liquid much resembling the methide in properties. Magnesium methide is a solid obtained, mixed with magnesium iodide, when magnesium filings or ribbon are heated in a sealed tube with methyl iodide and acetic ether, methyl iodide alone having no action. It is also obtained mixed with globules of mercury when magnesium is heated with mercury methide in a sealed tube. Its most remarkable properties are its intense action with water, incandescence usually occurring with ignition of the evolved gas; and its spontaneous inflammability in carbon dioxide, the combustion being accompanied by beautiful scintillations. The ethide is a very similar substance.

THE additions to the Zoological Society's Gardens during the past week include two Toque Monkeys (*Macacus pileatus*), a Starred Tortoise (*Testudo stellata*) from Ceylon, presented by Mr. W. J. Bosworth; a Peregrine Falcon (*Falco peregrinus*), British, presented by Mr. A. C. Ionides; a Humboldt's Lagothrix (*Lagothrix humboldti*) from the Upper Amazons, purchased.

OUR ASTRONOMICAL COLUMN.

SPECTROSCOPIC OBSERVATIONS OF SUN-SPOTS.—The *Monthly Notices of the Royal Astronomical Society* for December 1890 contains the main conclusions deduced by the Rev. A. L. Cortie, S.J., from the sun-spot observations made at the Stonyhurst College Observatory in the years 1882–89. The region of the spectrum in which observations have been made is between the lines B and D. The widening of the lines in the sun-spot spectra observed has generally been reckoned in tenths of their normal breadth, and are classified as "widened," "more widened," and "most widened," for comparison among themselves. At South Kensington only the six most widened lines in the spectrum of a sun-spot are recorded, hence the two sets of observations are not easily comparable. The interval 1882–89 has been divided into two periods in the discussion, viz. the disturbed period of solar activity extending from 1882–86, and the quiet period 1886–89.

In the disturbed period only one of the fifty-three iron lines in the region B—D was observed to have a mean widening. During the quiet period, however, many more iron lines appeared among the more widened. In this particular, therefore, Father Cortie's results confirm the conclusion arrived at by Prof. Lockyer in 1880 from a similar discussion. With respect to other substances, the observations show that seven out of the eleven titanium lines in the region studied were very much affected in the spot spectra at both periods, the lines most persistently widened being among the faintest Fraunhofer lines, and among the brighter of the metallic lines. The mean widening of calcium lines increased slightly during the minimum period. Sodium lines were much affected in the maximum epoch, especially in the large spots. Several lines given by Ångström as "telluric" have been seen widened. The C line has often appeared less dark over sun-spots, but when bright the reversal was generally due to faculæ between the spots. From a total of 2088 individual observations of other lines it is concluded that (1) About the maximum period a great number of faint lines not in Ångström are to be seen in sun-spots. (2) Such lines are not seen exclusively in maximum spots, but reappear in minimum spots when they are large. (3) Some faint lines which have been persistently watched are to be seen greatly widened in every sun-spot, large or small, whether in the disturbed or quiet period. (4) The mean widening of all the five bright chromospheric lines coincident with unknown lines in this region has been low. A Browning automatic spectroscope with a dispersion of twelve prisms of 60° was used for the observations.

TURIN OBSERVATORY.—Some publications of interest have recently been issued from this Observatory. Signor Porro gives the results of observations of the magnitude of the star U (Nova) Orionis throughout a whole period of variation. On November 21, 1889, the star was 8·81 mag.; on April 28, 1890, it was 8·80; and a maximum magnitude = 5·80 was observed on January 21, 1890. Mr. Chandler has given the period of this variable as 371 days, with a maximum on December 7, 1885. Signor Porro finds that the observations made in 1885, in conjunction with those now given, indicate a period of 378·5 days from the epoch December 7.

A large number of determinations of the latitude of Turin has also been made. The mean of 120 observations results in the value $\phi = 45° 4' 7''·942 \pm 0''·029$. The observations do not exhibit the periodic variation observed in the latitude observations made at Berlin, Potsdam, and Prague.

Convenient ephemerides for the sun and moon in 1891 have been calculated for the meridian of Turin by Signor Aschieri. The meteorological observations made in 1889 have been tabulated by Dr. G. B. Rizzo.

THE DUPLICITY OF α LYRÆ.—The duplication of the K line in some photographs of the spectrum of Vega taken by Mr. A. Fowler, and from which he inferred that the star was a spectroscopic double of the β Aurigæ type, has not been confirmed by photographs taken by Prof. Pickering, Prof. Vogel, and MM. Henry. Some other explanation must therefore be found to account for the phenomenon.

GASEOUS ILLUMINANTS.[1]

II.

ORDINARY coal gas of an illuminating power of 14 to 16 candles can be produced at a fairly low rate, but if a higher quality is required considerable additional expense has to be incurred in order to enrich it. Up to now, the material almost universally employed for this purpose has been cannel; but as this article is rapidly rising in price, and the best qualities are not easily obtainable, attention is being seriously directed to other means of bringing up the illuminating power of gas. This question of enrichment has been the study of inventors from the earliest days of the gas industry. The methods employed for this purpose may be classified as:—(1) The carburetting of low-power gas by impregnating it with the vapour of volatile hydrocarbons. (2) Enriching the gas by vapours and permanent gases obtained by the decomposition of the tar formed at the same time as the gas. (3) Mixing with the coal gas, oil gas obtained by decomposing crude oils by heat. (4) Mixing with the coal gas, water gas which has been highly carburetted by passing it, with the vapours of various hydrocarbons, through superheaters, in order to give permanency to the hydrocarbon gases.

In the first method, many points have to be taken into consideration, as the hydrocarbons which have from time to time been used for this purpose, vary so greatly in composition; a very volatile naphtha, although it evaporates quickly, and larger quantities of its vapour are taken up by the gas, often giving a less increase of luminosity than a heavier hydrocarbon of which but little is vaporized.

The great trouble which presented itself in the older carburetting systems was that all the commercial samples of naphtha are mixtures of various hydrocarbons, each having its own boiling-point, and that therefore, when used in any of the old forms of carburetters, they gave up their more volatile constituents very freely at the beginning of the experiment, while the amount rapidly diminished as the boiling-point of the residue became higher; so that when 2113 cubic feet of poor coal gas were passed through a naphtha having a specific gravity of 0·869 and a boiling-point of 103° C., the temperature during the experiment being 22° C., the first 80 cubic feet of gas took up 23·2 grains of the naphtha, while the last 450 cubic feet only took up 7·3 grains. Another difficulty found was the increase of evaporation with the rise in the temperature of the gas; as with an ordinary form of carburetter, exposed to atmospheric changes, the enrichment of the gas, which reached 54·4 per cent. in summer with an average temperature of 22° C., fell in winter to only 22 per cent. with an average temperature of 3° C. Of course, in these carburetters a good deal depended upon the form of apparatus; and it was found, on trying different shapes with the same naphtha, that when the gas merely flowed through a box containing a layer of it, only about 3·2 grains were taken up; while with a carburetter in which the naphtha was sucked up by cotton fibre, so as to expose a large surface to the gas, as much as 22 to 23 grains were absorbed. One of the most important points noticed during these experiments was, that it was only a poor gas which could be enriched in this manner, and that if a rich cannel gas was passed through the naphtha, it became robbed of some of its illuminating power.

It must be clearly borne in mind, in approaching this subject, that the evaporation of a hydrocarbon into a permanent gas—*i.e.*, a gas which does not liquefy within the ordinary range of temperature—is a question neither of specific gravity nor of boiling-point, although the latter has more to do with it than the former. It is purely a question of vapour tension. Most liquids, when left to themselves in contact with the atmosphere gradually pass into the state of vapour, and disappear; and those which evaporate most quickly are said to be most volatile. If ether, for example, is dropped upon an exposed surface, it at once disappears, and causes, by its evaporation, considerable cold; and the lightest forms of naphthas do the very same thing. But although this evaporation takes place with rapidity with liquids of low boiling-point, it must not be forgotten that even many solids have the same property—naphthalene, camphor, and iodine being cases in point. It must also be remembered that evaporation occurs over a very wide range of temperature; but that for each substance there is a limit below which evaporation does not seem to take place. So that, when considering the suitability of a liquid for carburetting in this way, it is far more important to determine its vapour tension than its specific gravity or its boiling-point.

So far all systems for carburetting gas with liquid hydrocarbons at the burners have proved failures, but in the albocarbon light the vapour of naphthalene is caused to mingle with the gas just before combustion, the volatilization being effected by a spur of metal heated by the flame itself, which conducts the heat back into a chamber containing solid naphthalene, through which the gas passes, and this process has proved very successful.

Any system to be generally adopted must be applied to the gas in bulk before distribution. In doing this, there are two factors to be considered: the vapour added must be in such proportion to the gases which have to carry them that no fear need exist of their being deposited by any sudden cooling of the gas;

[1] Continued from p. 235.

and care must be taken that the vapour added is not in sufficient quantity to throw out of suspension the volatile hydrocarbons in the gas. The carrying power of a gas depends upon its constituents; for in the same way that liquids vary in their power of dissolving and carrying—*i.e.*, keeping in solution—solids, so do gases vary in their power of bearing away the more volatile hydrocarbons. If the carrying power of air is taken as unity, then the power of ordinary coal gas is about 1·5, while hydrogen would be nearly 3·5; and it is manifest that attention must be paid to the ratio of the constituents present, if gases of varying composition are to be carburetted to the same degree.

During the past few months the idea of the possibility of carburetting coal gas in bulk has again been revived by the construction of an extremely ingenious apparatus, the outcome of the combined engineering skill and practical experience of Messrs. Maxim and Clark, which obviates, to a very great extent, the difficulties which arose with the older forms of carburetter. It has been shown that, when carburetting a gas with a gasoline or light naphtha spirit, the more volatile portions enrich the gas to an undue extent at first, and that, as the process continues, the amount taken up becomes gradually less. This would not so much matter in carburetting the gas in bulk before it went into the holder, as it would become to a great extent mixed by diffusion, and a gas of fairly even illuminating power would result; but the Maxim-Clark apparatus is intended not only to do this, but also to carburet the gas used in large establishments and works.

This apparatus is of such a form that in small installations the whole of the gas to be used can be passed through, and each portion supplied with its own share of hydrocarbon, whilst when carburetting gas in bulk a certain portion can be withdrawn from the main, carburetted and again return it to the main, where, mingling with the steady flow of gas, the whole becomes of uniform composition.

In the earliest days of the gas industry, attempts were made to utilize tar for the production and enrichment of gas; and the patent literature of the century contains many hundred such schemes, most of them being still-born, while a few spent a short and sickly existence, but none achieved success. The reason of this is not difficult to understand. In order to make gas from tar, two methods may be adopted: either to condense the tar in the ordinary way, and afterwards use the whole or portions of it for cracking into a permanent gas; or to crack the tar vapours before condensation by passing the gas and vapours through superheaters. If the first method is adopted, the trouble which at once presents itself, and in a few hours brings the apparatus to grief, is that tar contains 60 per cent. of pitch, which rapidly chokes and clogs up all the pipes; while, if an attempt is made to use a temperature at which the pitch itself is decomposed, it is found that a non-luminous or very poorly luminous gas is the result, and that a heavy deposit of carbon remains in the superheater and retort, and even at high temperatures easily condensable vapours escape, to afterwards create trouble in the pipes.

The most successful attempt to utilize certain portions of the liquid products of the distillation of coal is undoubtedly the Dinsmore process, in which the coal gas and the vapours which, if allowed to cool, would form tar, are made to pass through a heated chamber, and a certain proportion of otherwise condensable hydrocarbons are thus converted into permanent gases. Using a poor class of coal, it is claimed that 9800 cubic feet of 20 to 21 candle gas can be made by this process; while by the ordinary system 9000 cubic feet of 15-candle gas would have been produced.

In distilling the coal in the ordinary way, the yield of tar is 11 gallons per ton; but by the Dinsmore process only 7 gallons. On examining the analysis of the ordinary and Dinsmore tar, it is at once evident that the 4 gallons which have disappeared are the chief portions of the light oils and creosote oils; and these are the factors which have given the increase of illuminating power to the gas.

In enriching a poor coal gas by injecting paraffin oil into the retort during distillation, it must be borne in mind that, as the coal is undergoing distillation, in the earlier stages a rich gas is given off, while towards the end of the operation the gas is very poor in illuminants and rich in hydrogen; the methane disappearing with the other hydrocarbons, and the increase in hydrogen being very marked. Mr. Lewis T. Wright employed a coal requiring six hours for its distillation, and took samples of the gas at different periods of the time. On analysis, these yielded the following results:—

Time after commencement of distillation.	10 min.	1h. 30m.	3h. 25m.	5h. 35m.
Sulphuretted hydrogen...	1·30	1·42	0·49	0·11
Carbon dioxide	2·21	2·09	1·49	1·50
Hydrogen	20·10	38·33	52·68	67·12
Carbon monoxide	6·19	5·68	6·21	6·12
Marsh gas	57·38	44·03	33·54	22·58
Illuminants	10·62	5·98	3·04	1·79
Nitrogen...	2·20	2·47	2·55	0·78

This may be regarded as a fair example of the changes which take place in the quality of the gas during the distillation of the coal. In carburetting such a gas by injecting paraffin into the retort, it would be a great waste to do so for the first two hours, as a rich gas is being given off which has not the power of carrying a very much larger quantity of hydrocarbons—being practically saturated with them. Consequently, to make it take along with it, in a condition not easily deposited, any further quantity, the paraffin would have to be broken down to a great extent; and the temperature necessary to do this would seriously affect the quality of the gas being given off by the coal. When, however, the distillation had gone on for three hours, the rich portions of the coal gas would all have distilled off, and the temperature of the retort would have reached its highest point; and this would be the time to feed in the oil, as its cracking being an exothermic action, the temperature in the retort would be increased, and the gas rich in hydrogen which was being evolved would carry with it the oil gas, and prevent any re-deposition.

When carbon is acted upon at high temperatures by steam, the first action that takes place is the decomposition of the water vapour; the hydrogen being liberated, while the oxygen unites with the carbon to form carbon dioxide, thus—

$$\underset{\text{Carbon.}}{C} + \underset{\text{Water.}}{2(H_2O)} = \underset{\text{Carbon dioxide.}}{CO_2} + \underset{\text{Hydrogen.}}{2H_2}$$

The carbon dioxide so produced interacts with more red-hot carbon, forming the lower oxide, carbon monoxide, thus—

$$CO_2 + C = 2CO.$$

So that the completed reaction may be looked upon as yielding a mixture of equal volumes of hydrogen and carbon monoxide—both of them inflammable, but with non-luminous flames. This decomposition, however, is rarely completed, and a certain proportion of carbon dioxide is invariably to be found in the water gas, which, in practice, generally consists of a mixture of about the following composition:—

Hydrogen	48·31
Carbon monoxide	35·93
Carbon dioxide	4·25
Nitrogen	8·75
Methane	1·05
Sulphuretted hydrogen	1·20
Oxygen	0·51
	100·00

The above is an analysis of water gas made from gas coke in a Van Steenbergh apparatus. The ratio of carbon monoxide and carbon dioxide present depends entirely upon the temperature of the generator and the kind of carbonaceous matter employed. With a hard dense anthracite coal, for instance, it is quite possible to attain a temperature at which there is practically no carbon dioxide produced; while with an ordinary form of generator, and a loose fuel like coke, a large proportion is generally to be found. The sulphuretted hydrogen in the analysis quoted is, of course, due to the high amount of sulphur to be found in the gas coke, and is practically absent from water gas made with anthracite. The nitrogen is due to the method of manufacture; the coke being, in the first instance, raised to incandescence by an air-blast, which leaves the generator and pipes full of a mixture of nitrogen and carbon monoxide (producer gas), which is carried over by the first portions of water gas into the holder. The gas so made has no photometric value—its constituents being perfectly non-luminous; and attempts to use it as an illuminant have all taken the form of incandescent burners, in which thin "mantles" or "combs" of highly refractory metallic oxides are heated up to incandescence. In the case of carburetted water gas, the gas is only used as a carrier of illuminating hydrocarbon gases made by decomposing various grades of hydrocarbon oils into permanent gases by heat.

Water gas generators can be divided into two classes:—(1) Continuous processes, in which the heat necessary to bring about the interaction of the carbon and the steam is obtained by performing the operation in retorts externally heated in a furnace. (2) Intermittent processes, in which the carbon is first heated to incandescence by an air-blast, and the air-blast being cut off, superheated steam is blown in until the temperature is reduced to a point at which the carbon begins to fail in its action, when the air is again admitted to bring the fuel up to the required temperature; the process consisting of the alternate formation of producer gas with rise of temperature, and of water gas with lowering of temperature.

Of the first class of generator, none, so far, have as yet been practically successful in England.

Of the intermittent processes, the one most in use in America is the Lowe, in which the coke or anthracite is heated to incandescence by an air-blast in a generator lined with fire-brick; the heated products of combustion, as they leave the generator and enter the superheaters, being supplied with more air, which causes the combustion of the carbon monoxide present in the producer gas, and heats up the fire-brick baffles with which the superheaters are filled. When the necessary temperature of fuel and superheater has been reached, the air-blasts are cut off, and steam is blown through the generator, forming water gas, which meets the enriching oil at the top of the first superheater, called the "carburetter," and carries the vapours with it through the main superheater, where the firing of the hydrocarbons takes place. The chief advantage of this apparatus is that the enormous superheating space enables a lower temperature to be used for the fixing, which does away to a certain extent with the too great breaking down of the hydrocarbon, and consequent deposition of carbon.

The Springer apparatus differs from the Lowe only in construction. In the former the superheater is directly above the generator; and there is only one superheating chamber instead of two. The air-blast is admitted at the bottom, and the producer gases heat the superheater in the usual way; and when the required temperature is reached, the steam is blown in at the top of the generator, and is made to pass down through the incandescent fuel. The water gas is led from the bottom of the apparatus to the top, where it enters at the summit of the superheater, meets the oil, and passes down with it through the chamber, the finished gas escaping at the middle of the apparatus. This idea of making the air-blast pass up through the fuel, while in the subsequent operation the steam passes down through it, is also to be found in the Loomis plant, and is a distinct advantage—the fuel being at its hottest where the blast has entered, and, in order to keep down the percentage of carbon dioxide, it is important that the fuel through which the water gas last passes should be as hot as possible, to insure its reduction to carbon monoxide.

The Flannery apparatus is also only a slight modification of the Lowe plant, the chief difference being that, as the water gas leaves the generator, the oil is fed into it, and with the gas passes through a D-shaped retort tube, arranged round three sides of the top of the generator. In this tube the oil is volatilized, and passes with the gas to the bottom of the superheater, in which the vapours are converted into permanent gases.

The Van Steenbergh plant stands apart from all other forms of carburetted water gas plant, in that the upper layer of the fuel itself forms the superheater, and that no second part of any kind is needed for the fixation of the hydrocarbons. This arrangement reduces the apparatus to the simplest form, and leaves no part of it which can choke or get out of order—an advantage which will not be underrated by anyone who has had experience of these plants. While, however, an enormous advantage is gained, there is also the drawback that the apparatus is not at all fitted for use with crude oils of heavy specific gravity, such as can be dealt with in the big external superheaters of the Lowe class of water gas plant, but requires to have the lighter oils used in it for carburetting purposes. This, which appears at first sight to be a disadvantage, is not altogether one, as, in the first place, the lighter grade of oils, if judged by the amount of carburetting property they possess, are cheaper per candle-power added to the gas than the crude oils, while their use entirely does away with the formation of pitch and carbon in the pipes and purifying apparatus—a factor of the greatest importance to the gas manufacturers. The fact that light oils give a higher carburation per gallon than heavy crude oils is due to the fact that the crude oils have to be heated to a higher temperature to convert them into permanent gases; and this causes an over-cracking of the most valuable illuminating constituents. This trouble cannot be avoided, as, if a lower temperature is employed, the result is the formation of non-permanent vapours, which, by their condensation in the pipes, give rise to endless trouble. The simplicity of the apparatus is a factor which is a considerable saving of time and expense, as it reduces to a minimum the risk of stoppages for repairs, while the initial cost of the apparatus is necessarily low, and the expense of keeping it in order practically *nil*.

In such an apparatus 1000 cubic feet of carburetted water gas, having an illuminating value of 22 candles, can be made with the consumption of about 30 pounds of coke or anthracite and 2·5 gallons of light naphtha.

The great objection to the use of carburetted water gas is undoubtedly the poisonous nature of the carbon monoxide, which acts by diffusing itself through the air-cells of the lungs, and forming with the colouring of the blood corpuscles a definite compound, which prevents them carrying off their normal function of taking up oxygen and distributing it throughout the body, and at once stops life. All researches on this subject point to the fact that something less than 1 per cent. only of carbon monoxide in air renders it fatal to animal life; and this at first sight seems to be an insuperable objection to the use of water gas. It has, indeed, influenced the authorities in several towns—notably Paris—to forbid the introduction of water gas for domestic consumption. It would be well, however, to carefully examine the subject, and see, by the aid of actual figures, what the risk amounts to, compared with the risks of ordinary coal gas. Many experiments have been made with the view of determining the percentage of carbon monoxide in air which is fatal to human or rather to animal life, the most trustworthy as well as the latest results being those obtained by Dr. Stevenson, of Guy's Hospital, after an investigation instituted in consequence of two deaths which took place at the Leeds Forge, from inhaling uncarburetted water gas containing 40 per cent. of carbon monoxide. Dr. Stevenson found that 1 per cent. visibly affected a mouse in 1½ minutes, and killed it in an hour and three-quarters, while 0·1 per cent. was highly injurious. Taking, for the sake of argument, the last figure as being a fatal quantity, so as to be well within the mark, it is found that in ordinary carburetted water gas, as supplied by the superheater processes, such as the Lowe, Springer, and others, the usual amount of carbon monoxide is 26 per cent.; but in the Van Steenbergh gas, for certain chemical reasons to be discussed later on, it is generally about 18 per cent., and rarely rises to 20 per cent. An ordinary bedroom is 12 feet by 15 feet and 10 feet high; and therefore it will contain 1800 cubic feet of air. Such a room would be lighted by a single ordinary batswing burner, consuming not more than 4 cubic feet of gas per hour. And if this were left full on, in one hour the 1800 cubic feet of air would be mixed with four-fifths of a cubic foot of carbon monoxide (the carburetted water gas being supposed to contain 20 per cent.) or 0·04 per cent. In such a room, however, if the doors and windows were absolutely air-tight, and there were no fire-place, diffusion through the walls would change the entire air once in an hour. Therefore the percentage would not rise above 0·04; while in any ordinary room, imperfect workmanship and an open chimney would change it four times in the hour, and reduce the percentage to 0·01—a quantity which the most inveterate enemy of water gas could not claim would do more than produce a bad headache. The point under consideration, however, was the use of carburetted water gas as an enricher of coal gas, and not as an illuminant to be consumed *per se*; and it might be calculated that it would be probably used to enrich a 16-candle coal gas up to 17·5-candle power. To do this, 25 per cent. of 12-candle power carburetted water gas would have to be mixed with it. Taking the quantity of carbon monoxide in London gas at 5 per cent. (a very fair average figure), and 18 per cent. as the amount present in the Van Steenbergh gas, we have 8·25 per cent. of carbon monoxide in the gas as sent out—a percentage hardly exceeding that which is found in the rich cannel gas supplied to such places as Glasgow, where it is not found that an unusual number of deaths occur from carbon monoxide poisoning. Moreover, carburetted water gas has quite as strong a smell as coal gas, and can be quite as easily detected by the nose.

The cost of most of these methods of enriching coal gas can be calculated, and give the following figures as the cost of enriching a 16-candle gas up to 17·5-candle power per 1000 cubic feet:—

By cannel coal	4*d.*
By the Maxim-Clark process	$2\frac{6}{10}$*d.*
By the Lowe or Springer water gas	$1\frac{1}{2}$*d.*
By the Van Steenbergh water gas	$\frac{3}{4}$*d.*

In adopting any new method, the mind of the gas manager must, to a great extent, be influenced by the circumstances of the times; and the enormous importance of the labour question is a main factor at the present moment. With masters and men living in a strained condition, which may at any moment break into open warfare, the adoption of such water gas processes would relieve the manager of a burden which is growing almost too heavy to be borne. Combining, as such processes do, the maximum rate of production with the minimum amount of labour, they practically solve the labour question.

The cost of paraffin oil of lighter grades, and the fear that the supply might be hampered by the formation of a huge monopoly, has been a great drawback, but we have materials which can be equally well used in this country of which an almost unlimited supply can be obtained.

At three or four of the Scotch iron-works, the Furnace Gases Company are paying a yearly rental for the right of collecting the smoke and gases from the blast-furnaces. These are passed through several miles of wrought-iron tubing, gradually diminishing in size from 6 feet to about 18 inches; and as the gases cool there is deposited a considerable yield of oil. At Messrs. Dixon's, in Glasgow, which is the smallest of these installations, they pump and collect about 60,000,000 feet of furnace gas per day, and recover, on an average, 25,000 gallons of furnace oils per week; using the residual gases, consisting chiefly of carbon monoxide, as fuel for distilling and other purposes, while a considerable yield of sulphate of ammonia is also obtained. In the same way a small percentage of the coke-ovens are fitted with condensing gear, and produce a considerable yield of oil, for which, however, there is but a very limited market; the chief use being for the Lucigen light, and other lamps of the same description, and also for pickling timber for railway sleepers, &c. The result is that four years ago the oil could be obtained in any quantity at $\frac{1}{2}$*d.* per gallon; though it has since been as high as $2\frac{1}{2}$*d.* per gallon. It is now about 2*d.* per gallon, and shows a falling tendency. Make a market for this product, and the supply will be practically unlimited, as every blast-furnace and coke-oven in the kingdom will put up plant for the recovery of the oil. As, with the limited plant now at work, it would be perfectly easy to obtain 4,000,000 or 5,000,000 gallons per annum, an extension of the recovery process would mean a supply sufficiently large to meet all demands.

Many gas managers have from time to time tried if they could not use some of their creosote oil for producing gas; but, on heating it in retorts, &c., they have found that the result has generally been a copious deposit of carbon, and a gas which has possessed little or no illuminating value. Now the furnace and coke-oven oils are in composition somewhat akin to the creosote oil; so that, at first sight, it does not seem a hopeful field for search after a good carburetter. But the furnace oils have several points in which they differ from the coal-tar products. In the first place, they contain a certain percentage of paraffin oil; and, in the next, do not contain much naphthalene, in which the coal-tar oil is especially rich, and which would be a distinct drawback to their use. The furnace oil, as condensed, contains about 30 to 50 per cent. of water; and, in any case, this has to be removed by distilling. Mr. Staveley has patented a process by which the distillation is continued after the water has gone off, and by condensing in a fractionating column of special construction, he is able to remove all the paraffin oil, a considerable quantity of cresol, a small quantity of phenol, and about 10 per cent. of pyridine bases, leaving the remainder of the oil in a better condition, and more valuable for pickling timber, its chief use.

If the mixed oil so obtained, which we may call "phenoloid oil," is cracked by itself, no very striking result is obtained; the 40 per cent. of paraffin present cracking in the usual way, and yielding a certain amount of illuminants. But if the oil is cracked in the presence of carbon, and is made to pass over and through a body of carbon heated to a dull red heat, it is converted largely into benzene. As this is the most valuable of the illuminants in coal gas, and also the one to which it owes the largest proportion of its light-giving power, it is manifestly the right one to use in order to enrich it. On cracking the phenoloid oil, the paraffin yields ethane, propane, and marsh gas, &c., in the usual way; while the phenol interacts with the carbon to form benzene:—

$$\underset{\text{Phenol.}}{C_6H_5HO} + C = \underset{\text{Benzene.}}{C_6H_6} + CO.$$

And in the same way the cresol first breaks down to toluene in the presence of the carbon; and this in turn is broken down by the heat to benzene. A great advantage this oil has is that the flashing-point is 110° C., and so is well above the limit; this doing away with the dangers and troubles inseparable from the storage of light naphthas in bulk.

In using this oil as an enricher, it must be cracked in the presence of carbon; and it is of the greatest importance that the temperature should not be too high, as the benzene is easily broken down to simpler hydrocarbons of far lower illuminating value.

(To be continued.)

SCIENTIFIC SERIALS.

American Journal of Science, December 1890.—Long Island Sound in the Quaternary era, with observations on the submarine Hudson River channel, by James D. Dana. The discussion of a chart containing some new soundings recently made under the direction of the U.S. Coast and Geodetic Survey leads Prof. Dana to conclude that during the Glacial period "Long Island Sound, instead of being, as it is now, an arm of the ocean twenty miles wide, was for the greater part of its length a narrow channel serving as a common trunk for the many Connecticut and some small Long Island streams, and that the southern Sound river reached the ocean through Peconic Bay. Under these circumstances the supply of fresh water for the Sound river would have been so great that salt water would have barely passed the entrance of the Sound." He attributes the origin of the channel over the submerged Atlantic border to the flow of the Hudson River during a time of emergence.—The preservation and accumulation of cross-infertility, by John T. Gulick. The author discusses some of the conclusions arrived at by Mr. Wallace in his work on "Darwinism."—The deformation of Iroquois Beach and birth of Lake Ontario, by J. W. Spencer. The author believes that the great Iroquois Beach was constructed approximately at sea-level and that its upheaval was the means that gave birth to Lake Ontario. This episode commenced almost synchronously with the creation of the Niagara Falls.—Experiments upon the constitution of the natural silicates, by F. W. Clarke and E. A. Schneider.—Eudialyte and eucolite, from Magnet Cove, Arkansas, by J. Francis Williams.—Prediction of cold waves from Signal Service weather maps, by T. Russell. In addition to the regular fall of temperature that takes place from day to night, irregular falls occur from time to time. When the fall in the latter case exceeds 20°, and covers an area greater than 50,000 square miles, and the temperature in any part of the area falls as low as 36°, it is called a cold wave. The author has investigated the shapes and relative positions of the various high and low areas of pressure preceding cold waves, and proposes a method for the prediction of them.—On a peculiar method of sand transportation by rivers, by James C. Graham. Numerous blotches of sand, some about six inches square, have been observed floating on the surface of the Connecticut River. This indicates that, by surface tension, it is possible for coarse sand to be floated away on a current having less velocity than would otherwise be required, and affords a possible explanation of the coarser particles of sand usually found in otherwise very fine deposits.—Note on the Cretaceous rocks of Northern California, by J. S. Diller.—Magnetic and gravity observations on the west coast of Africa and at some islands in the North and South Atlantic, by E. D.

Preston.—On the Fowlerite variety of rhodonite from Franklin and Stirling, N.J., by L. V. Pirsson.—Some observations on the beryllium minerals from Mount Antero, Colorado, by S. L. Penfield.

Royal Society, December 11, 1890.—"On Stokes's Current Function." By R. A. Sampson, Fellow of St. John's College, Cambridge. Communicated by Prof. Greenhill, F.R.S.

In a liquid any irrotational motion which is symmetrical about an axis may be regarded as due to the juxtaposition at the origin and upon the axis of symmetry of sinks and sources.

Let us consider the system formed by a line source and a line sink, of equal strengths, extending along the axis from an arbitrary origin to infinity in opposite directions. Such a system I shall call an *extended doublet*, of strength m, where m is the strength per unit length of that part which lies on the positive side of the origin.

By the superposition of two extended doublets, of equal but opposite strengths, we can produce a sink or a source upon the axis. Hence, in a liquid, any irrotational motion which is symmetrical with respect to an axis may be produced by superposition of extended doublets, whose origins depart but little from an arbitrary point on the axis of symmetry.

Now, for an extended doublet of strength m, we find Stokes's current function ψ, for any point distant r from the origin $= -2mr$. Whence, if $r\sin\theta = \varpi$, $r\cos\theta = z - \zeta$, $\mu = \cos\theta$

$$\frac{d^2\psi}{d\varpi^2} + \frac{d^2\psi}{dz^2} - \frac{1}{\varpi}\frac{d\psi}{d\varpi} = 0 = \frac{d^2\psi}{dr^2} + \frac{1-\mu^2}{r^2}\frac{d^2\psi}{d\mu^2}.$$

Thus it will be seen that the direct distance of any point from a point on the axis of symmetry plays the same part in the theory of Stokes's current function that is played by its reciprocal in the theory of the potential function belonging to symmetrical distributions of matter.

And if r_0, 0, r, θ, be the co-ordinates of a point upon the axis, and of any other point, the distance between these points, $\sqrt{(r_0^2 - 2r_0r\cos\theta + r^2)}$, may be developed in a convergent series, say

$$\sum_{n=0}^{n=\infty} - \frac{r^n}{r_0^{n-1}} I_n(\cos\theta),$$

or

$$\sum_{n=0}^{n=\infty} - \frac{r_0^n}{r^{n-1}} I_n(\cos\theta),$$

according as r_0 is greater or less than r, $I_n(\cos\theta)$ being a certain function of θ, satisfying

$$(1-\mu^2)\frac{d^2 I_n(\mu)}{d\mu^2} + n(n-1)I_n(\mu) = 0.$$

It is evident from the analogue of zonal harmonics that it is proper to discuss the function $I_n(\cos\theta)$, and other solutions of this equation, before considering the applications of Stokes's current function to the motion of liquids. As might be expected, the theory closely resembles that of spherical harmonics.

The applications to hydrodynamics which I here give are chiefly in connection with the motion of viscous liquids. In *Crelle-Borchardt*, vol. lxxxi., 1876, Oberbeck has given the velocities produced in an infinite viscous liquid by the steady motion of an ellipsoid through it, in the direction of one of its axes, and from these Mr. Herman (*Quart. Journ. Math.*, 1889, No. 92) has found the equation of a family of surfaces containing the stream lines relative to the ellipsoid. I obtain Stokes's current function by a direct process for the flux of a viscous liquid past a spheroid, and it is shown that the result differs only by a constant multiple from the particular case of Mr. Herman's integral.

Some minor applications are also given—namely, the solutions are obtained for flux past an approximate sphere, and past an approximate spheroid. The solution is also obtained for flux through a hyperboloid of one sheet, where it appears that the stream surfaces are hyperboloids of the confocal system. A particular case is that of flux through a circular hole in a wall, and this is interesting because we see that, by supposing internal friction to take place in the liquid, we find an expression which gives zero velocity at the sharp edge, and thus avoids the difficulty which is always present in the solution of such problems on the supposition that the liquid is perfect.

The paper concludes with an attempt to discuss the flux past a spheroid, or through a hyperboloid at whose boundary there may be slipping. The current function is not obtained, all that appears being that it probably differs from the parallel case of the sphere in being far more complicated than when there is no slipping. From this we except the case of the flux through a circular hole in a plane wall, when the solution for no slipping satisfies the new conditions.

Chemical Society, November 6, 1890.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The magnetic rotation of saline solutions, by Dr. W. H. Perkin, F.R.S. The remarkable results given by solutions of the halhydrides and their compounds with ammonia and organic bases when examined as to their magnetic rotatory power (Chem. Soc. Trans., 1889, 740) made it important to study the solutions of metallic salts in a similar manner. The substances which have been examined up to the present are chiefly chlorides, bromides, iodides, nitrates, a nitrite, sulphates, and phosphates, also hydroxides of alkali metals. For haloid metallic salts in aqueous solution, the rotations were found to be practically 2·2 times greater than the calculated values for the dry substances, and greater therefore than those of the analogous ammonium compounds. A similar remarkable increase of rotation was observed with the hydroxides of the alkali metals, but with sulphates and phosphates numbers agreeing much more closely with the calculated values were obtained. In the discussion which followed the reading of the paper, Dr. Gladstone, F.R.S., said that similar excessive values were obtained on determining the refractive powers of solutions of metallic chlorides, &c., although the differences between the calculated and observed values were much smaller than in the case of Dr. Perkin's measurements. It was all-important to determine the difference in behaviour to light of a substance in its solid state and when in solution, but this was difficult as few solids were uniaxial; as an example of the difference he mentioned that in the case of sodium chloride the solid has a refraction of 14·4, while that of the dissolved substance is 15·3.—Note on normal and isopropylparatoluidine, by Mr. E. Hori and Dr. H. F. Morley.—The action of light on ether in the presence of oxygen and water, by Dr. A. Richardson. In a recent paper by Dunstan and Dymond (Chem. Soc. Trans., 1890, 574) it is stated that hydrogen peroxide is not formed when carefully purified ether is exposed at a low temperature in contact with air and water to the electric light or diffused daylight. Employing ether which had been purified by some of the methods of Dunstan and Dymond, the author found that hydrogen peroxide is formed in the liquid in every case after exposure to sunlight in contact with moist air or oxygen, but not in the dark at the ordinary temperature.—Action of ammonia and methylamine on the oxylepidens, by Dr. F. Klingemann and Mr. W. F. Laycock.—Condensation of acetone-phenanthraquinone, by Mr. G. H. Wadsworth.—Action of phosphorus pentachloride on mucic acid, by Dr. S. Ruhemann and Mr. S. F. Dufton.—Halogens and the asymmetrical carbon atom, by Mr. F. H. Easterfield. The author has endeavoured to prepare optically active haloid derivatives similar in constitution to Le Bel's optically active secondary amyl iodide, which at present stands alone as the only active compound in which a halogen is united to the asymmetric carbon atom. The results obtained with optically active mandelic acid were negative.

November 20.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—A new method of determining the specific volumes of liquids and of their saturated vapours, by Prof. S. Young. When a tube closed at both ends and partly filled with a liquid is raised in temperature, the liquid expands, but the apparent expansion is less than the real, for a certain amount of the substance separates and occupies the space above the liquid in the form of saturated vapour. If the density of the vapour were known, it would be possible to apply the necessary correction; but at high temperatures and pressures this is not the case. If, on the other hand, the upper part of the tube (enclosing the vapour and a portion of the liquid) be heated to a high temperature, the lower part being kept at a constant low temperature, and if subsequently a greater length of the tube be heated to the high temperature, there will again be expansion, but in this case the observed expansion will be greater than the real, for in consequence of the diminution in volume of the saturated vapour, a portion of it must have condensed. In both cases there are the same two unknown values, the true volume of the liquid and the specific volume of the vapour, and from the two equations involving the experimental data it is, therefore, possible to calculate both values. The experimental method based on these principles possesses the following advantages: it is applicable to substances such as nitrogen peroxide or bromine which attack mercury; it is available for a very wide range of temperature and pressure, even to the critical point of many substances; the data obtained serve to determine not only the specific volume of the liquid, but also that of its saturated vapour.—The molecular condition of metals when alloyed with each other, by Messrs. C. T. Heycock and F. H. Neville. The authors in their earlier experiments (Chem. Soc. Journ., 1890, 376) showed that one atomic proportion of a metal when dissolved in tin produces a fall in the freezing-point that on the theory of osmotic pressure should be produced by one molecular proportion, and therefore concluded that when metals are dissolved in tin their molecules are monatomic. Further experiments with other metals as solvents have led to the following results:—Of fourteen metals dissolved in bismuth, seven (viz. lead, thallium, mercury, tin, palladium, platinum, and cadmium) have monatomic molecules; of fifteen metals dissolved in cadmium, seven (viz. antimony, platinum, bismuth, tin, sodium, lead, and thallium) have monatomic molecules; and of fourteen metals dissolved in lead, five (viz. gold, palladium, silver, platinum, and copper) have monatomic, and three (viz. mercury, bismuth, and cadmium) have diatomic molecules.—The estimation of cane sugar, by Messrs. C. O'Sullivan, F.R.S., and F. W. Tompson.—The spectra of blue and yellow chlorophyll, with some observations on leaf-green, by Prof. W. N. Hartley, F.R.S. The author draws the following conclusions from the results of his investigation of the different colouring-matters described under the name chlorophyll:—(1) Living tissues which are fresh and young, and which therefore contain the leaf-green unaltered, exhibit no trace of a band close to D, such as is usually attributed to chlorophyll, and there is no indication of one in the green. (2) Yellow chlorophyll has a distinct absorption-band in the red differing from that of blue chlorophyll. It has likewise a distinct fluorescence. (3) When light is concentrated on living tissues the absorption spectrum of the green colouring-matter is soon altered. (4) Blue chlorophyll may be extracted from minced leaves by cold absolute alcohol, and may be precipitated by addition of baryta. Yellow chlorophyll is not so precipitated, or not precipitated so readily. A warm solution of boracic acid in glycerine, mixed with a little alcohol, liberates the unchanged blue chlorophyll from the dried barium compound. (5) Blue chlorophyll exhibits two absorption-bands in the red, close together; in the less refrangible region of rays one overlies B and the other overlies C. There is a feebler band near D. (6) Concentrated solutions of yellow chlorophyll in benzene are brownish in colour, and exhibit a magnificent red fluorescence. (7) When blue and yellow chlorophyll are separately treated with formic acid and ether, there are produced two new substances showing absorption-bands in the green. It is believed that when these bands have been observed, either in preparations of chlorophyll or in living tissues, the chlorophyll has been altered by oxidation of formic aldehyde in the plant. This oxidation could be caused in living tissues by an excessive degree of illumination, which causes the destruction of the tissues, and otherwise by exposure of the contents of the plant-cells to air or oxygen. An excessive illumination causes an exceedingly great activity in decomposing carbonic acid, and probably oxygen cannot be respired sufficiently rapidly; hence there may be a reverse action, or an oxidation of formic aldehyde to formic acid. (8) The leading characteristics of unaltered leaf-green are those of blue chlorophyll—namely, an intense absorption in the red, stronger even than in the violet or ultra-violet.—Note on dibenzanilide, by Dr. J. B. Cohen.

December 4.—Dr. W. J. Russell, F.R.S., President, in the chair.—The following papers were read:—The action of heat on ethylic β-amidocrotonate, by Dr. J. N. Collie.—The action of heat on nitrosyl chloride, by Messrs. J. J. Sudborough and G. H. Miller. An account is given of a series of determinations of the vapour-density of nitrosyl chloride at various temperatures. At temperatures from 15° to 693°, the values obtained so nearly coincide with the theoretical value 32·67 that it is to be supposed that no dissociation takes place below 700°. At higher temperatures the compound is no longer stable. The results show that in comparison with nitrogen dioxide, which is completely decomposed below 620°, nitrosyl chloride is a highly stable compound.—The volumetric estimation of tellurium, by Dr. B. Brauner.
